PREFACE

In the more than 95 years since the first edition of the *Cecil Textbook of Medicine* was published, almost everything we know about internal medicine has changed. Progress in medical science is now occurring at an ever-accelerating pace, and it is doing so within the framework of transformational changes in biomedical science, clinical practice, and the delivery of health care at individual, societal, and global levels. This textbook and its associated electronic products incorporate the latest medical knowledge in multiple formats that should appeal to students and seasoned practitioners, regardless of how they prefer to access this rapidly changing information.

Even as *Cecil*'s specific information has changed, however, we have remained true to the tradition of a comprehensive textbook of medicine that carefully explains the *why* (the underlying genetics, genomics, and pathobiology of disease) and the *how* (now expected to be evidence-based from randomized controlled trials and meta-analyses). Descriptions of physiology and pathophysiology include the latest genetic advances in a practical format that strives to be useful to the nonexpert so that care can truly be as precise and personalized as possible.

Medicine has entered an era when the acuity of illness and the limited time available to evaluate a patient threaten the ability of physicians to satisfy their intellectual curiosity. As a result, the acquisition of information, quite easily achieved in this era, is often confused with knowledge. We have attempted to address this dilemma with a textbook that not only informs but also stimulates new questions and gives a glimpse of the future path to new knowledge. Grade A evidence is specifically highlighted in the text and referenced at the end of each chapter.

In addition to the information provided in the printed textbook and its electronic version, *Cecil* is commonly accessed on Elsevier's electronic Clinical Key platform. *Cecil* content and graphics are specifically organized to optimize not only its readability but also the searchability and utility of these electronic versions, which are continuously updated to incorporate new Grade A references and other evidence.

The section for each organ system begins with a chapter that summarizes an approach to patients with suspected or known dysfunction of that organ system. As summarized in E-Table 1-1, the text specifically provides clear, concise information regarding how a physician should approach more than 150 common symptoms, signs, and laboratory abnormalities, usually with a flow diagram, a table, or both for easy reference. In this way, *Cecil* remains a comprehensive text to guide diagnosis and therapy, not only for patients with suspected or known diseases, but also for patients who may have undiagnosed symptoms or signs that require an initial evaluation.

Just as each edition brings new authors, it also reminds us of our gratitude to past editors and authors. Previous senior editors of *Cecil* include a short but remarkably distinguished group of leaders of American medicine: Russell Cecil, Robert Loeb, Paul Beeson, Walsh McDermott, James Wyngaarden, Lloyd H. Smith, Jr., Fred Plum, J. Claude Bennett, Dennis Ausiello, and Andrew Schafer. As we welcome a group of outstanding new editors—Kathleen A. Cooney, Kirsten Bibbins-Domingo, Victoria J. Fraser, Ali G. Gharavi, Anthony N. Hollenberg, and S. Claiborne Johnston—we also express our appreciation to Robert C. Griggs, Donald W. Landry, Wendy Levinson, W. Michael Scheld, Allen M. Spiegel, and other associate editors from previous editions on whose foundation we continue to build. Our returning associate editors—Mary K. Crow, Nancy E. Davidson, Jeffrey M. Drazen, Anil K. Rustgi—continue to make critical contributions to the selection of authors and the review and approval of all chapters in their respective sections.

The tradition of *Cecil* is that all chapters are written by distinguished experts in each field. All told, our 409 chapters and the Appendix are written by approximately 570 individual authors. Steven A. Seifert, an author of the chapter on "Envenomation, Bites, and Stings," passed away after submitting his chapter, and we deeply mourn his passing.

The editors are most grateful for the superb editorial assistance of Maribel Lim, who expertly coordinated a team that included Caroline Davidson, Pamela Ehn, Julie Mangoff, and Joan Dupont, and without whose dedication, perseverance, and attention to detail this book never would have been possible. At Elsevier, we are most indebted to Dolores Meloni, Laura Schmidt, Daniel Fitzgerald, and Maggie Reid—dedicated professionals who have been critical to the planning and production of this edition.

This edition of *Goldman-Cecil Medicine* includes many new authors. We would also like to thank outgoing authors, who often provided figures that are included in this edition as well as tables that have been included or modified for this edition. Furthermore, because of the templated format and extensive editing that are characteristic of *Goldman-Cecil Medicine*, some new chapters incorporate principles, concepts, and organizational aspects from those prior chapters, often revised extensively prior to publication. Prior authors whose 26th edition coauthors have revised and updated their chapters include: Jeffrey L. Anderson, Gerald B. Appel, David Atkins, Richard L. Barbano, Stephen G. Baum, Hasan Bazari, George A. Beller, Paul D. Berk, Philip J. Bierman, Michael R. Bishop, William A. Blattner, William Bonnez, David M. Buchner, Edgar M. Carvalho, Troy E. Daniels, W. Lawrence Drew, George L. Drusano, David O. Freedman, John N. Galgiani, Jeffrey S. Ginsberg, Colleen Hadigan, Frederick G. Hayden, Douglas C. Heimburger, Edward W. Hook, III, Michael R. Jaff, Alain Joffe, Sian Jones, Carol A. Kauffman, Anthony E. Lang, Geoffrey S.F. Ling, Kieren A. Marr, Eric L. Matteson, William J. McKenna, Theodore E. Nash, Lindsay E. Nicolle, David L. Paterson, Srinivasa N. Raja, Daniel E. Rusyniak, George Sakoulas, Robert A. Salata, William Schaffner, W. Michael Scheld, Harry Shamoon, Richard M. Siegel, David P. Steensma, Raymond A. Strikas, and Ronald B. Turner. Special thanks also to Morton J. Kern, Gary S. Firestein, and Stephanie M. Stanford, whose excellent chapters were eliminated to save space, with their key information shortened and incorporated into other chapters. We also thank other non-returning authors from the 26th edition, many of whom had contributed to multiple editions: Grover C. Bagby, Thomas P. Bleck, Olaf A. Bodamer, Patrick J. Bosque, Lucy Breakwell, John C. Byrd, Clara Camaschella, Jane A. Cauley, William P. Cheshire, Jr., Arun Chockalingam, Steven L. Cohn, David S. Cooper, Joseph Craft, Mark R. Cullen, Stephen C. Dreskin, Thomas D. DuBose, Jr., Herbert L. DuPont, George M. Eliopoulos, Jerrold J. Ellner, Joel D. Ernst, Gregory T. Everson, Amelia Evoli, Martyn A. French, Susan I. Gerber, Dale N. Gerding, Matthew R. Golden, Richard M. Gore, Leslie C. Grammer, M. Lindsay Grayson, Lev M. Grinberg, Rajesh Gupta, H. Hunter Handsfield, David J. Hunter, Karen R. Jacobson, Stuart Johnson, Jacqueline Jonklaas, Gerald T. Keusch, Alexander Kratz, Virginia Byers Kraus, Frank A. Lederle, William M. Lee, James E. Leggett, Glenn N. Levine, Marc S. Levine, Bennett Lorber, Daniel R. Lucey, Peter Manu, Xavier Mariette, Thomas J. Marrie, Emeran A. Mayer, Stephan A. Mayer, Graeme Meintjes, Jonathan W. Mink, William E. Mitch, Bruce A. Molitoris, José G. Montoya, Daniel M. Musher, Stanley J. Naides, Anne T. Neff, Anne B. Newman, Gaetane Nocturne, James R. O'Dell, Pablo C. Okhuysen, Pankaj Jay Pasricha, Manisha Patel, Michael A. Pesce, James D. Ralston, Adam J. Ratner, Susan E. Reef, David B. Reuben, Karen Rosene-Montella, Renato M. Santos, Sam Schulman, Wun-Ju Shieh, Michael S. Simberkoff, Eric J. Small, Magdalena E. Sobieszczyk, Roland W. Sutter, Ronald G. Victor, Angela Vincent, Tonia L. Vincent, Edward H. Wagner, John T. Watson, David A. Weinstein, Anita K.M. Zaidi, Sherif Zaki, and Thomas Ziegler. We also thank Peter S. Aronson, who contributed to the chapter on "Acid-Base Disorders"; Ghada Hijazi, who contributed to the chapter on "Glycogen Storage Diseases"; Alexander Hillel, who contributed to the chapter on "Throat Disorders"; and Jason Pan, who contributed to the chapter on "Hepatic Failure and Liver Transplantation." Chapters written by public employees reflect recommendations and conclusions of

the authors and do not necessarily reflect the official position of the entity for which they work.

My work on this and previous editions would not have been possible without mentors such as Robert Gifford, Eugene Braunwald, P. Roy Vagelos, and the late Lloyd H. Smith, Jr. I am also especially indebted to Jill and the entire Goldman family (Jeff, Abigail, Mira, Samuel, Daniel, Morgan, Quincy, Robyn, Tobin, Dashel, and Alden), who have not only tolerated but actually inspired the countless hours required to edit a book that attempts to sustain the *Cecil* tradition and to meet the needs of today's physicians.

Sharon C-A Chen, MB BS, PhD
Clinical Professor of Medicine, The University of Sydney Centre for Infectious Diseases and Microbiology, Westmead Hospital, Westmead, New South Wales, Australia
Cryptococcosis

Susan Y. Chon, MD
Professor of Dermatology, University of Texas MD Anderson Cancer Center, Houston, Texas
Urticaria, Drug Hypersensitivity Rashes, Nodules and Tumors, and Atrophic Diseases

David C. Christiani, MD
Professor of Medicine, Harvard Medical School; Physician, Pulmonary and Critical Care, Massachusetts General Hospital; Elkan Blout Professor of Environmental Genetics, Environmental Health, Harvard School of Public Health, Boston, Massachusetts
Physical and Chemical Injuries of the Lung

Edward Chu, MD, MMS
Carol and Roger Einiger Professor of Cancer Medicine; Director, Montefiore Einstein Cancer Center; Vice-President of Cancer Medicine; Albert Einstein College of Medicine and Montefiore Medicine, Bronx, New York
Neoplasms of the Small and Large Intestine

Theodore J. Cieslak, MD, MPH
Adjunct Associate Professor of Epidemiology, College of Public Health, University of Nebraska, Omaha, Nebraska
Bioterrorism

George A. Cioffi, MD
Edward S. Harkness Professor and Chair, Jean and Richard Deems Professor of Ophthalmology, Columbia University Vagelos College of Physicians and Surgeons, New York, New York
Diseases of the Visual System

Carolyn M. Clancy, MD
Assistant Undersecretary for Health, Discovery, Education and Affiliate Networks, Department of Veterans Affairs; Clinical Associate Professor of Internal Medicine, George Washington University School of Medicine and Health Sciences, Washington, D.C.
Measuring Health and Health Care

Heather Clauss, MD
Professor of Internal Medicine/Infectious Disease, Lewis Katz School of Medicine at Temple University, Philadelphia, Pennsylvania
Gram-Positive Rod Infections

Daniel J. Clauw, MD
Professor of Anesthesiology, Medicine (Rheumatology) and Psychiatry, and Director, Chronic Pain and Fatigue Research Center, University of Michigan Medical School, Ann Arbor, Michigan
Fibromyalgia

David R. Clemmons, MD
Kenan Professor of Medicine, University of North Carolina School of Medicine; Attending Physician, UNC Hospitals, Chapel Hill, North Carolina
Approach to the Patient with Endocrine Disease

Thomas M. Coffman, MD
Professor and Dean, Cardiovascular and Metabolic Disorders Program, Duke-NUS Medical School, Singapore; James R Clapp Professor of Medicine, Duke University School of Medicine, Durham, North Carolina
Vascular Disorders of the Kidney

David Cohen, MA, MD
Daniel Midler-John A. Catsimatidis Professor of Nephrology, Professor of Medicine, Columbia University Vagelos College of Physicians and Surgeons, New York, New York
Treatment of Irreversible Renal Failure

Jeffrey Cohen, MD
Chief, Laboratory of Infectious Diseases, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, Maryland
Varicella-Zoster Virus (Chickenpox, Shingles)

Myron S. Cohen, MD
Yeargan-Bate Eminent Professor of Medicine, Microbiology and Epidemiology; Associate Vice Chancellor for Global Health; Director, Institute of Global Health and Infectious Diseases, University of North Carolina School of Medicine, Chapel Hill, North Carolina
Approach to the Patient with a Sexually Transmitted Infection; COVID-19: Epidemiology, Clinical Manifestations, Diagnosis, Community Prevention, and Prognosis; Prevention of Human Immunodeficiency Virus Infection

Steven P. Cohen, MD
Professor of Anesthesiology & Critical Care Medicine, Neurology, and Physical Medicine & Rehabilitation, and Psychiatry and Behavioral Sciences and Chief, Pain Medicine Division, Johns Hopkins School of Medicine, Baltimore, Maryland; Director of Pain Research and Professor of Anesthesiology and Physical Medicine & Rehabilitation, Walter Reed National Military Medical Center, Uniformed Services University of the Health Sciences, Bethesda, Maryland
Pain

Joseph M. Connors, MD
Emeritus Professor, BC Cancer Centre for Lymphoid Cancer and the University of British Columbia, Vancouver, British Columbia, Canada
Hodgkin Lymphoma

Deborah J. Cook, MD, MSc
Professor of Medicine, Clinical Epidemiology & Biostatistics, McMaster University Michael G. DeGroote School of Medicine, Hamilton, Ontario, Canada
Approach to the Patient in a Critical Care Setting

Lucy B.M. Cook, MB BS, PhD
Consultant Hematologist, Centre for Haematology, Faculty of Medicine, Imperial College London, London, United Kingdom
Retroviruses Other Than Human Immunodeficiency Virus

Kathleen A. Cooney, MD
George Barth Geller Distinguished Professor and Chair, Department of Medicine, Duke University School of Medicine, Durham, North Carolina
Approach to Medicine, the Patient, and the Medical Profession: Medicine as a Learned and Humane Profession; Prostate Cancer

William J. Craigen, MD, PhD
Professor of Molecular and Human Genetics, Baylor College of Medicine, Houston, Texas
Approach to Inborn Errors of Metabolism

Jill P. Crandall, MD
Jacob and Jeanne Barkey Professor of Medicine and Chief, Division of Endocrinology, Albert Einstein College of Medicine, New York, New York
Diabetes Mellitus

Simon L. Croft, PhD, DSc
Emeritus Professor, Faculty of Infectious and Tropical Diseases, London School of Hygiene & Tropical Medicine, London, United Kingdom
Leishmaniasis

Mary K. Crow, MD
Professor of Medicine, Weill Medical College of Cornell University; Mary K. Crow, MD Chair in Immunology and Inflammation Research, Hospital for Special Surgery, New York, New York
Approach to Medicine, the Patient, and the Medical Profession: Medicine as a Learned and Humane Profession; The Innate and Adaptive Immune Systems; Approach to the Patient with Rheumatic Disease; Systemic Lupus Erythematosus

John A. Crump, MB ChB, MD, DTMH
Professor of Medicine, Pathology, and Global Health, Centre for International Health, University of Otago, Dunedin, Otago, New Zealand
Salmonella *Infections (Including Enteric Fever)*

Merit E. Cudkowicz, MD
Julieanne Dorn Professor of Neurology, Harvard Medical School and Chair of Neurology, Massachusetts General Hospital, Boston, Massachusetts
Amyotrophic Lateral Sclerosis and Other Motor Neuron Diseases

Charlotte Cunningham-Rundles, MD, PhD
David S Gottesman Professor of Medicine, Icahn School of Medicine at Mount Sinai, New York, New York
Primary Immunodeficiency Diseases

Kathryn M. Dahir, MD
Professor of Medicine, Director of the Program for Metabolic Bone Disorders at Vanderbilt, Vanderbilt University Medical Center, Nashville, Tennessee
Osteonecrosis, Osteosclerosis/Hyperostosis, and Other Disorders of Bone

Inger K. Damon, MD, PhD
Director, Retired, Division of High Consequence Pathogens and Pathology, Centers for Disease Control and Prevention, Atlanta, Georgia
Smallpox, Monkeypox, and Other Poxvirus Infections

Michael Daras, MD, PhD
Professor of Neurology, Columbia University Vagelos College of Physicians and Surgeons, New York, New York
Nutritional and Alcohol-Related Neurologic Disorders

Richard C. Dart, MD, PhD
Professor of Emergency Medicine, University of Colorado School of Medicine and Director, Rocky Mountain Poison and Drug Safety, Denver Health and Hospital Authority, Denver, Colorado
Envenomation, Bites, and Stings

Nancy E. Davidson, MD
Professor of Medicine, Raisbeck Endowed Chair, and Chief, Division of Medical Oncology, University of Washington School of Medicine; Executive Vice President, Fred Hutchinson Cancer Center, Seattle, Washington
Approach to Medicine, the Patient, and the Medical Profession: Medicine as a Learned and Humane Profession; Breast Cancer and Benign Breast Disorders

Kevin D. Deane, MD, PhD
Professor of Medicine, University of Colorado School of Medicine, Aurora, Colorado
Laboratory Testing in the Rheumatic Diseases

Lisa M. DeAngelis, MD
Chief Physician Executive, Memorial Sloan Kettering Cancer Center, New York, New York; Professor of Neurology, Weill Medical College of Cornell University, New York, New York
Tumors of the Central Nervous System

Malcolm M. DeCamp, MD
Professor of Surgery and Chair, Division of Cardiothoracic Surgery; K. Craig Kent Chair in Strategic Leadership, University of Wisconsin School of Medicine and Public Health, Madison, Wisconsin
Interventional and Surgical Approaches to Lung Disease

Thomas G. DeLoughery, MD
Professor of Hematology, Oregon Health & Science University, Portland, Oregon
Microcytic and Hypochromic Anemias

Carlos del Rio, MD
Leon L. Haley Jr MD Distinguished Professor of Medicine, Emory University School of Medicine; Professor of Epidemiology and Global Health, Rollins School of Public Health of Emory University, Atlanta, Georgia
COVID-19: Epidemiology, Clinical Manifestations, Diagnosis, Community Prevention, and Prognosis; Prevention of Human Immunodeficiency Virus Infection

Gabriele C. De Luca, MD, DPhil
Professor of Clinical Neurology and Experimental Neuropathology, Nuffield Department of Clinical Neurosciences, University of Oxford, Oxford, Oxfordshire, United Kingdom
Approach to the Patient with Neurologic Disease

David W. Denning, MBBS
Professor of Infectious Diseases in Global Health, The University of Manchester, Manchester, United Kingdom
Systemic Antifungal Agents

Patricia A. Deuster, PhD, MPH
Professor and Executive Director, Consortium for Health and Military Performance, Uniformed Services University, Bethesda, Maryland
Rhabdomyolysis

Amy E. DeZern, MD, MHS
Associate Professor of Oncology and Medicine, Johns Hopkins University School of Medicine, Baltimore, Maryland
Aplastic Anemia and Related Bone Marrow Failure States

Ketan K. Dhatariya, MBBS, MSc, MD, MS, PhD
Honorary Professor of Medicine, Norwich Medical School, University of East Anglia; Consultant, Elsie Bertram Diabetes Centre, Norfolk and Norwich University Hospitals NHS Foundation Trust, Norwich, Norfolk, United Kingdom
Diabetes Mellitus

A L G r a w a n y

Robert B. Diasio, MD
William J. and Charles H. Mayo Professor of Molecular Pharmacology and Experimental Therapeutics, Mayo Clinic College of Medicine and Science, Rochester, Minnesota
Principles of Drug Therapy

David J. Diemert, MD
Professor, Departments of Medicine and of Microbiology, Immunology and Tropical Medicine, George Washington University School of Medicine and Health Sciences, Washington, D.C.
Nematode Infections

Kathleen B. Digre, MD
Distinguished Professor of Neurology and Professor of Ophthalmology, University of Utah School of Medicine, Salt Lake City, Utah
Headaches and Other Head Pain

Vasken Dilsizian, MD
Professor of Medicine and Radiology, Department of Diagnostic Radiology and Nuclear Medicine, University of Maryland School of Medicine; Chief, Division of Nuclear Medicine, University of Maryland Medical Center, Baltimore, Maryland
Noninvasive Cardiac Imaging

Jodie A. Dionne, MD
Associate Professor of Medicine, University of Alabama at Birmingham, Birmingham, Alabama
Syphilis and Nonsyphilitic Treponematoses

Jorge Di Paola, MD
Professor of Pediatrics and Elizabeth Finney McDonnell Endowed Chair and Director, Division of Pediatric Hematology Oncology, Washington University School of Medicine in St. Louis, St. Louis, Missouri
Von Willebrand Disease and Hemorrhagic Abnormalities of Platelet and Vascular Function

Angela Dispenzieri, MD
Professor of Medicine and of Laboratory Medicine, Mayo Clinic College of Medicine and Science, Rochester, Minnesota
Amyloidosis

Sunil Dogra, MD, DNB
Professor of Dermatology, Venereology and Leprology, Postgraduate Institute of Medical Education and Research (PGIMER), Chandigarh, India
Leprosy (Hansen Disease)

James H. Doroshow, MD
Deputy Director for Clinical and Translational Research and Director, Division of Cancer Treatment and Diagnosis, National Cancer Institute, National Institutes of Health, Bethesda, Maryland
Approach to the Patient with Cancer

John M. Douglas, Jr., MD
Executive Director, Tri-County Health Department, Greenwood Village, Colorado
Papillomavirus

Jeffrey M. Drazen, MD
Distinguished Parker B. Francis Professor of Medicine, Harvard Medical School; Senior Physician, Department of Medicine, Brigham and Women's Hospital; Editor, NEJM Group, Boston, Massachusetts
Approach to Medicine, the Patient, and the Medical Profession: Medicine as a Learned and Humane Profession; Asthma

Dimitri Drekonja, MD, MS
Associate Professor of Medicine, University of Minnesota; Chief, Infectious Diseases Section, Minneapolis VA Health Care System, Minneapolis, Minnesota
Approach to the Patient with Urinary Tract Infection

Erik R. Dubberke, MD, MSPH
Professor of Medicine, Washington University School of Medicine in St. Louis, St. Louis, Missouri
Clostridial and Clostridioides *Infections*

Catherine E. DuBeau, MD
Professor of Medicine, Geisel School of Medicine at Dartmouth-Hitchcock Medical Center, Lebanon, New Hampshire
Urinary Incontinence

J. Stephen Dumler, MD
Professor and Chairperson, Joint Departments of Pathology, Uniformed Services University, Walter Reed National Military Medical Center, and Joint Pathology Center, Bethesda, Maryland
Zoonoses

Madeleine Duvic, MD
Professor and Deputy Chairman, Department of Dermatology, University of Texas MD Anderson Cancer Center, Houston, Texas
Urticaria, Drug Hypersensitivity Rashes, Nodules and Tumors, and Atrophic Diseases

Kristie Ebi, PhD, MPH
Professor of Global Health, University of Washington Center for Health and the Global Environment (CHanGE), Schools of Medicine and Public Health, University of Washington, Seattle, Washington
Effects of Climate Change on Health

Kathryn M. Edwards, MD
Sarah H. Sell and Cornelius Vanderbilt Endowed Chair and Professor of Pediatrics, Vanderbilt University School of Medicine, Nashville, Tennessee
Parainfluenza Viral Disease

N. Lawrence Edwards, MD
Professor and Vice Chairman, Department of Medicine, University of Florida; Chief, Section of Rheumatology, Malcolm Randall Veterans Administration Medical Center, Gainesville, Florida
Crystal Deposition Diseases

John W. Eikelboom, MBBS, MSc
Professor of Medicine, McMaster University Michael G. DeGroote School of Medicine, Hamilton, Ontario, Canada
Venous Thrombosis and Embolism

Lawrence H. Einhorn, MD
Distinguished Professor of Medicine, Indiana University School of Medicine, Indianapolis, Indiana
Testicular Cancer

Perry M. Elliott, MBBS, MD
Professor of Cardiovascular Medicine, Institute of Cardiovascular Science, University College London & St. Bartholomew's Hospital, London, United Kingdom
Diseases of the Myocardium and Endocardium

Ezekiel J. Emanuel, MD, PhD
Diane v.S. Levy & Robert M. Levy Professor and Vice Provost for Global Initiatives, University of Pennsylvania, Philadelphia, Pennsylvania
Bioethics in the Practice of Medicine

Matthew E. Falagas, MD, MSc, DSc
Director, Alfa Institute of Biomedical Sciences and Director, First Department of Internal Medicine, Hygeia Hospital, Athens, Greece; Adjunct Associate Professor of Medicine, Tufts University School of Medicine, Boston, Massachusetts
Pseudomonas *and* Burkholderia *Infections*

Gary W. Falk, MD, MS
Professor of Medicine, University of Pennsylvania Perelman School of Medicine, Philadelphia, Pennsylvania
Diseases of the Esophagus

James C. Fang, MD
June and John Hartman Presidential Endowed Chair, Professor, and Chief, Division of Cardiovascular Medicine, University of Utah School of Medicine; Executive Director, Cardiovascular Service Line, University of Utah Health Sciences, Salt Lake City, Utah
ST-Elevation Acute Myocardial Infarction and Complications of Myocardial Infarction

Monica M. Farley, MD
Jonas A. Shulman Professor of Medicine and Director, Division of Infectious Diseases, Emory University School of Medicine, Atlanta, Georgia
Haemophilus *and* Moraxella *Infections*

Gene Feder, MBBS, MD
Professor of Primary Care, Centre for Academic Primary Care, Population Health Sciences, Bristol Medical School, University of Bristol, Bristol, United Kingdom
Intimate Partner Violence

David J. Feller-Kopman, MD
Professor of Medicine, Geisel School of Medicine; Chief, Pulmonary and Critical Care Medicine, Dartmouth Hitchcock Medical Center, Lebanon, New Hampshire
Interventional and Surgical Approaches to Lung Disease

Thomas McDonald File, Jr., MD, MSc
Professor of Medicine and Chair, Infectious Disease Section, Northeast Ohio Medical University, Rootstown, Ohio; Chair, Infectious Disease Division, Summa Health, Akron, Ohio
Streptococcus pneumoniae *Pulmonary Infections*

Glenn I. Fishman, MD
William Goldring Professor of Medicine and Director, Leon H. Charney Division of Cardiology, New York University Grossman School of Medicine, New York, New York
Principles of Electrophysiology

John M. Flack, MD, MPH
Sergio Rabinovich Endowed Chair of Internal Medicine, Professor and Chair, Department of Medicine, Southern Illinois University, Springfield, Illinois
Arterial Hypertension

James M. Fleckenstein, MD
Professor of Medicine & Molecular Microbiology, Washington University School of Medicine in St. Louis, St. Louis, Missouri
Approach to the Patient with Suspected Enteric Infection

Lee A. Fleisher, MD
Emeritus Professor and Former Chair, Anesthesiology and Critical Care, University of Pennsylvania Perelman School of Medicine, Philadelphia, Pennsylvania
Overview of Anesthesia

Paul W. Flint, MD
Professor and Chair of Otolaryngology-Head & Neck Surgery, Oregon Health & Science University, Portland, Oregon
Throat Disorders

Evan L. Fogel, MD, MSc
Stuart Sherman Professor of Gastroenterology and Hepatology and Professor of Medicine, Indiana University School of Medicine, Indianapolis, Indiana
Diseases of the Gallbladder and Bile Ducts

Robert J. Fontana, MD
Professor of Medicine, University of Michigan Medical School, Ann Arbor, Michigan
Liver Failure and Transplantation

Chris E. Forsmark, MD
Professor of Medicine, University of Florida College of Medicine, Gainesville, Florida
Pancreatitis

Pierre-Edouard Fournier, MD, PhD
Professor of Medical Bacteriology-Virology and Hygiene, Aix-Marseille Universite and Institut Hospitalo-Universitaire Mediterranee-Infection, Marseille, France
Rickettsial Infections

Vance G. Fowler, Jr., MD, MHS
Florence McAlister Distinguished Professor of Medicine and of Molecular Genetics and Microbiology, Duke University School of Medicine, Durham, North Carolina
Infective Endocarditis

Manuel A. Franco, MD, PhD
Professor, Instituto de Genética Humana, Facultad de Medicina, Pontificia Universidad Javeriana, Bogotá, Colombia
Rotaviruses, Noroviruses, and Other Gastrointestinal Viruses

Victoria J. Fraser, MD
Adolphus Busch Professor and Chair, Department of Medicine, Washington University School of Medicine in St. Louis, St. Louis, Missouri
Approach to Medicine, the Patient, and the Medical Profession: Medicine as a Learned and Humane Profession; Introduction to Microbial Disease: Pathophysiology and Diagnostics; Legionella *Infections*

Roy Freeman, MD
Professor of Neurology, Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, Massachusetts
Autonomic Disorders

Karen M. Freund, MD, MPH
Professor of Medicine and Vice Chair for Faculty Affairs and Quality Improvement, Tufts University School of Medicine, Boston, Massachusetts
Approach to Women's Health

Blake A. Froberg, MD
Associate Professor of Pediatrics and Emergency Medicine, Indiana University School of Medicine, Indianapolis, Indiana
Chronic Poisoning: Trace Metals and Others

Patrick G. Gallagher, MD
Professor of Pediatrics, Pathology and Genetics, Yale University School of Medicine, New Haven, Connecticut
Hemolytic Anemias: Red Blood Cell Membrane and Metabolic Defects

Monica Gandhi, MD
Professor of Medicine and Director of the Ward 86 HIV Clinic, University of California, San Francisco School of Medicine, San Francisco, California
COVID-19: Epidemiology, Clinical Manifestations, Diagnosis, Community Prevention, and Prognosis

Rajesh T. Gandhi, MD
Professor of Medicine, Harvard Medical School; Director of HIV Clinical Services and Education, Massachusetts General Hospital, Boston, Massachusetts
COVID-19 Treatment and Vaccination

Leonard Ganz, MD
Division Vice President, Medical Affairs and Chief Medical Officer, Cardiac Rhythm Management Division Abbott, Beaver, Pennsylvania
Electrocardiography

Hasan Garan, MD, MS
Dickinson W. Richards, Jr. Professor of Medicine, Columbia University Vagelos College of Physicians and Surgeons, New York, New York
Ventricular Arrhythmias

Guadalupe Garcia-Tsao, MD
Professor of Medicine, Yale University School of Medicine, New Haven, Connecticut and VA-CT Healthcare System, West Haven, Connecticut
Cirrhosis and Its Sequelae

William M. Geisler, MD, MPH
Professor of Medicine, University of Alabama at Birmingham Heersink School of Medicine, Birmingham, Alabama
Diseases Caused by Chlamydiae

Joel M. Gelfand, MD, MSCE
James J. Leyden Professor of Dermatology and Epidemiology and Vice Chair, Clinical Research, Departments of Dermatology and of Biostatistics, Epidemiology, and Informatics, University of Pennsylvania Perelman School of Medicine, Philadelphia, Pennsylvania
Eczemas, Photodermatoses, Papulosquamous (Including Fungal) Diseases, and Figurate Erythemas

Tony P. George, MD
Professor of Psychiatry, University of Toronto; Clinician-Scientist, Centre for Addiction and Mental Health, Toronto, Ontario, Canada
Nicotine and Tobacco

Lior Gepstein, MD, PhD
Sohnis Family Professor in Medicine, Technion - Israel Institute of Technology; Director, Cardiology Department, Rambam Health Care Campus, Haifa, Israel
Regenerative Medicine, Cell Therapy, and Gene Therapy

Morie A. Gertz, MD
Roland Seidler Jr. Professor of the Art of Medicine and Chair Emeritus, Internal Medicine, Mayo Clinic College of Medicine and Science, Rochester, Minnesota
Amyloidosis

ALGrawany

Khalil G. Ghanem, MD, PhD
Professor of Medicine, Johns Hopkins University School of Medicine, Baltimore, Maryland
Syphilis and Nonsyphilitic Treponematoses

Ali G. Gharavi, MD
Jay Meltzer Professor and Chief, Division of Nephrology, Columbia University Vagelos College of Physicians and Surgeons, New York, New York
Approach to Medicine, the Patient, and the Medical Profession: Medicine as a Learned and Humane Profession; Approach to the Patient with Renal Disease

Cybele Ghossein, MD
Professor of Medicine and Vice Chair for Academic and Faculty Affairs, Northwestern University Feinberg School of Medicine, Chicago, Illinois
Interstitial Nephritis

Christopher J. Gill, MD, MS
Professor of Global Health, Boston University School of Public Health, Boston, Massachusetts
Whooping Cough and Other Bordetella *Infections*

Geoffrey S. Ginsburg, MD, PhD
Chief Medical and Scientific Officer, All of Us Research Program, National Institutes of Health, Bethesda, Maryland
Applications of Molecular Technologies to Clinical Medicine

Marshall J. Glesby, MD, PhD
Professor of Medicine, Weill Medical College of Cornell University, New York, New York
Systemic Manifestations of HIV/AIDS

John W. Gnann, Jr., MD
Professor of Medicine, Medical University of South Carolina, Charleston, South Carolina
Herpes Simplex Virus Infections

David L. Goldman, MD
Associate Professor of Pediatrics, Microbiology and Immunology, Children's Hospital at Montefiore/Albert Einstein College of Medicine, Bronx, New York
Mycoplasma *Infections*

Lee Goldman, MD, MPH
Cournand and Richards Professor of Cardiology, Columbia University Vagelos College of Physicians and Surgeons; Professor of Epidemiology, Mailman School of Public Health; Dean Emeritus, Faculties of Health Sciences and Medicine, Columbia University Irving Medical Center, New York, New York
Approach to Medicine, the Patient, and the Medical Profession: Medicine as a Learned and Humane Profession; Approach to the Patient with Possible Cardiovascular Disease; Bradycardias and Conduction System Delays; Supraventricular Ectopy and Tachyarrhythmias

Larry B. Goldstein, MD
Ruth L. Works Professor and Chair, Department of Neurology, and Associate Dean for Clinical Research, University of Kentucky College of Medicine; Co-Director, Kentucky Neuroscience Institute, Lexington, Kentucky
Approach to Cerebrovascular Diseases; Ischemic Cerebrovascular Disease

Anthony C. Gordon, MBBS, MD
Professor of Anesthesia & Critical Care, Imperial College London, London, United Kingdom
Shock Syndromes Related to Sepsis

Jason Gotlib, MD, MS
Professor of Medicine, Stanford University School of Medicine, Stanford Cancer Institute, Stanford, California
Polycythemia Vera, Essential Thrombocythemia, and Primary Myelofibrosis

Eduardo Gotuzzo, MD
Professor Emeritus, Alexander von Humboldt Tropical Medicine Institute, Universidad Peruana Cayetano Heredia; Principal Professor of Medicine and Tropical Diseases, National Hospital Cayetano Heredia, Lima, Peru
Cholera and Other Vibrio *Infections*

Hartmut Grasemann, MD, PhD
Professor of Pediatrics, The Hospital for Sick Children and University of Toronto, Toronto, Ontario, Canada
Cystic Fibrosis

Judith Green-McKenzie, MD, MPH
Professor, Division of Occupational & Environmental Medicine, Department of Emergency Medicine, University of Pennsylvania Perelman School of Medicine, Philadelphia, Pennsylvania
Principles of Occupational and Environmental Medicine

Harry B. Greenberg, MD
Professor of Medicine and of Microbiology and Immunology, Stanford University School of Medicine, Stanford, California
Rotaviruses, Noroviruses, and Other Gastrointestinal Viruses

Steven A. Greenberg, MD
Professor of Neurology, Brigham and Women's Hospital and Harvard Medical School, Boston, Massachusetts
Inflammatory Myopathies

David M. Greer, MD, MA
Professor and Chair of Neurology, Boston University Chobanian and Avedisian School of Medicine and Boston Medical Center, Boston, Massachusetts
Coma, Disorders of Consciousness, and Brain Death

S. Ryan Greysen, MD, MHS
Associate Professor of Medicine and Chief, Section of Hospital Medicine, University of Pennsylvania Perelman School of Medicine, Philadelphia, Pennsylvania
Medical Care of Patients with Psychiatric Diseases

Marie R. Griffin, MD, MPH
Professor Emerita of Health Policy, Vanderbilt University School of Medicine, Nashville, Tennessee
Overview of Pneumonia

Robert C. Griggs, MD
Professor of Neurology, Medicine, Pediatrics, Pathology & Laboratory Medicine, University of Rochester School of Medicine & Dentistry, Rochester, New York
Approach to the Patient with Neurologic Disease

Daniel Grossman, MD
Professor of Obstetrics, Gynecology and Reproductive Sciences, University of California, San Francisco School of Medicine, San Francisco, California
Contraception

Lisa M. Guay-Woodford, MD
McGehee Joyce Professor of Pediatrics, George Washington University School of Medicine and Health Sciences, Children's National Research Institute, Washington, D.C.
Hereditary Nephropathies and Developmental Renal/Urinary Abnormalities

Roy M. Gulick, MD, MPH
Rochelle Belfer Professor of Medicine and Chief, Division of Infectious Diseases, Weill Medical College of Cornell University; Attending Physician, New York-Presbyterian Hospital, New York, New York
Antiretroviral Treatment of Human Immunodeficiency Virus Infection

David A. Haake, MD
Health Sciences Clinical Professor of Medicine, David Geffen School of Medicine at UCLA; Staff Physician, VA Greater Los Angeles Healthcare System, Health Sciences, Los Angeles, California
Leptospirosis

Melissa M. Hagman, MD
Associate Professor of Medicine and Program Director, Internal Medicine Residency-Boise, University of Washington, Boise, Idaho
Nonpneumococcal Streptococcal Infections and Rheumatic Fever

Klaus D. Hagspiel, MD
Professor of Radiology, Medicine (Cardiology) and Pediatrics; Chief, Division of Noninvasive Cardiovascular Imaging, Department of Radiology and Medical Imaging, University of Virginia School of Medicine, Charlottesville, Virginia
Noninvasive Cardiac Imaging

Raymond C. Harris, MD
Anne and Roscoe R. Robinson Chair, Professor of Medicine, and Associate Chair, Division of Nephrology, Vanderbilt University School of Medicine, Nashville, Tennessee
Diabetes and the Kidney

Fiona P. Havers, MD, MHS
Medical Epidemiologist, National Center for Immunization and Respiratory Diseases, Centers for Disease Control and Prevention, Atlanta, Georgia
Pre-2019 Coronaviruses

Elisabeth I. Heath, MD
Professor of Oncology and Associate Director, Translational Sciences, Department of Oncology, Wayne State University School of Medicine, Karmanos Cancer Institute, Detroit, Michigan
Prostate Cancer

Frederick M. Hecht, MD
Professor of Medicine, University of California, San Francisco School of Medicine, San Francisco, California
Complementary and Integrative Medicine

Donald D. Hensrud, MD, MPH
Associate Professor of Preventive Medicine and Nutrition, Mayo Clinic College of Medicine and Science, Rochester, Minnesota
Diet and Nutrition

Jeremy Hess, MD, MPH
Professor of Emergency Medicine, University of Washington Center for Health and the Global Environment, Schools of Medicine and Public Health, University of Washington, Seattle, Washington
Effects of Climate Change on Health

Erik L. Hewlett, MD
Professor Emeritus of Medicine and of Microbiology, Immunology and Cancer Biology, University of Virginia School of Medicine, Charlottesville, Virginia
Whooping Cough and Other Bordetella *Infections*

Richard J. Hift, MMed, PhD
Professor of Medicine, University of KwaZulu-Natal, Durban, KwaZulu-Natal, South Africa
The Porphyrias

David R. Hill, MD, DTM&H
Professor of Medical Sciences and Director, Global Public Health, Quinnipiac University Frank H Netter MD School of Medicine, Hamden, Connecticut
Giardiasis

Nicholas S. Hill, MD
Professor of Medicine, Tufts University School of Medicine; Chief, Division of Pulmonary, Critical Care and Sleep Medicine, Tufts Medical Center, Boston, Massachusetts
Respiratory Monitoring in Critical Care

Christopher D. Hillyer, MD
President and Chief Executive Officer, New York Blood Center; Professor of Medicine, Weill Medical College of Cornell University, New York, New York
Transfusion Medicine

Hans H. Hirsch, MD, MSc
Professor and Senior Clinical Consultant, Transplantation & Clinical Virology, Department of Biomedicine, University of Basel; Division of Infectious Diseases & Hospital Epidemiology, Department of Acute Medicine, University Hospital Basel, Basel, Switzerland
Polyomaviruses

Marius M. Hoeper, MD
Professor of Respiratory Medicine, Hannover Medical School, Hannover, Germany
Pulmonary Hypertension

Brian D. Hoit, MD
Professor of Medicine, Physiology and Biophysics, Case Western Reserve University School of Medicine; Director of Echocardiography, Harrington Heart & Vascular Center, University Hospital Cleveland Medical Center, Cleveland, Ohio
Pericardial Diseases

V. Michael Holers, MD
Professor of Medicine and Immunology, University of Colorado School of Medicine, Aurora, Colorado
Complement System in Disease

Steven M. Holland, MD
Director, Division of Intramural Research and Chief, Immunopathogenesis Section, National Institute of Allergy and Infectious Diseases, NIH, Bethesda, Maryland
The Nontuberculous Mycobacteria

Anthony N. Hollenberg, MD
John Wade Professor and Chair, Department of Medicine, Boston University Chobanian & Avedisian School of Medicine; Physician-in-Chief, Boston Medical Center, Boston, Massachusetts
Approach to Medicine, the Patient, and the Medical Profession: Medicine as a Learned and Humane Profession; Thyroid

Steven M. Hollenberg, MD
Professor of Medicine, Emory University School of Medicine; Director, Cardiac Intensive Care, Emory Heart & Vascular Center, Atlanta, Georgia
Cardiogenic Shock

Jo Howard, MB BChir
Consultant Haematologist and Lead Clinician, Haematology, Guy's and St Thomas' National Health Service Foundation Trust; Honorary Professor, King's College London, London, United Kingdom
Sickle Cell Disease and Other Hemoglobinopathies

David J. Hunter, MBBS, MSc, M SpMed, PhD
Florance and Cope Chair of Rheumatology and Co-Director, Sydney Musculoskeletal Health Flagship, University of Sydney, Sydney, Australia
Osteoarthritis

Khalid Hussain, MB ChB, MD, MSc
Professor of Pediatrics, Weill Medical College of Cornell University-Qatar; Division Chief-Endocrinology, Department of Pediatrics, Sidra Medicine, Doha, Qatar
Hypoglycemia

Michael C. Iannuzzi, MD, MBA
Deputy Dean, Professor, and Chair of the Department of Medical Education, City University of New York School of Medicine, New York
Sarcoidosis

Robert D. Inman, MD
Professor of Medicine and Immunology, University of Toronto and Schroeder Arthritis Institute, University Health Network, Toronto, Ontario, Canada
Spondyloarthritis

Sharon K. Inouye, MD, MPH
Professor of Medicine, Harvard Medical School; Director, Aging Brain Center, Marcus Institute for Aging Research-Hebrew SeniorLife, Boston, Massachusetts
Delirium and Changes in Mental Status

Michael G. Ison, MD, MS
Chief, Respiratory Diseases Branch, Division of Microbiology and Infectious Diseases, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Rockville, Maryland
Influenza; Adenovirus Diseases

Joanna C. Jen, MD, PhD
Professor of Neurology, Otolaryngology, Neurosurgery, Icahn School of Medicine at Mount Sinai, New York, New York
Neuro-Ophthalmology; Smell and Taste; Hearing and Equilibrium

Dennis M. Jensen, MD
Professor of Medicine, David Geffen School of Medicine at UCLA; Staff Physician, VA Greater Los Angeles Healthcare System; Director, Human Studies Core & GI Hemostasis Research Unit, CURE Digestive Diseases Research Center, Los Angeles, California
Gastrointestinal Hemorrhage

Michael D. Jensen, MD
Professor of Medicine, Mayo Clinic College of Medicine and Science, Rochester, Minnesota
Obesity

Robert T. Jensen, MD
Chief, Cell Biology Section, Digestive Diseases Branch, National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health, Bethesda, Maryland
Neuroendocrine Neoplasms

ALGrawany

S. Claiborne Johnston, MD, PhD
Adjunct Professor of Neurology, University of California, San Francisco School of Medicine, San Francisco, California
Approach to Medicine, the Patient, and the Medical Profession: Medicine as a Learned and Humane Profession; Approach to the Patient with Neurologic Disease

Robin L. Jones, MD, BSc, MB
Professor of Medical Oncology and Head of the Sarcoma Unit, Royal Marsden Hospital and Institute of Cancer Research, London, United Kingdom
Malignant Bone Tumors, Sarcomas, and Other Soft Tissue Neoplasms

Richard C. Jordan, DDS, PhD
Professor of Pathology, Oral Pathology & Radiation Oncology, University of California, San Francisco School of Medicine, San Francisco, California
Diseases of the Mouth and Salivary Glands

Charles J. Kahi, MD, MS
Professor of Medicine, Indiana University School of Medicine, Indianapolis, Indiana
Vascular Diseases of the Gastrointestinal Tract

Laurent Kaiser, MD
Professor of Medicine and Head of the Infectious Disease Division, Geneva University Hospital (HUG), Geneva, Switzerland
Viral Hemorrhagic Fevers

Henry J. Kaminski, MD
Meta A. Neumann Professor of Neurology & Rehabilitation Medicine, George Washington University School of Medicine and Health Sciences, Washington, D.C.
Disorders of Neuromuscular Transmission

Moses R. Kamya, MBChB, MMed, MPH, PhD
Professor of Medicine, Makerere University, Kampala, Uganda; Executive Director, Infectious Diseases Research Collaboration, Kampala, Uganda
Malaria

Louise W. Kao, MD
Professor of Clinical Emergency Medicine and Director, Medical Toxicology Fellowship Program, Indiana University School of Medicine, Indianapolis, Indiana
Chronic Poisoning: Trace Metals and Others

Steven A. Kaplan, MD
Professor of Urology, Icahn School of Medicine at Mount Sinai; Director, Men's Health Program, Mount Sinai Health System, New York, New York
Benign Prostatic Hyperplasia and Prostatitis

Daniel L. Kastner, MD, PhD
NIH Distinguished Investigator and Scientific Director Emeritus, Division of Intramural Research, National Human Genome Research Institute, National Institutes of Health, Bethesda, Maryland
The Systemic Autoinflammatory Diseases

David A. Katzka, MD
Professor of Medicine, Columbia University Vagelos College of Physicians and Surgeons, New York, New York
Diseases of the Esophagus

Debra K. Katzman, MD
Professor of Pediatrics, The Hospital for Sick Children and University of Toronto; Senior Associate Scientist, Research Institute; The Hospital for Sick Children, Toronto, Ontario, Canada
Adolescent Medicine

Kenneth Kaushansky, MD
Professor of Medicine and Dean Emeritus, Renaissance School of Medicine at Stony Brook University, Stony Brook, New York
Hematopoiesis and Hematopoietic Growth Factors

Keith S. Kaye, MD, MPH
Professor of Medicine, Rutgers Robert Wood Johnson Medical School, New Brunswick, New Jersey
Diseases Caused by Acinetobacter *and* Stenotrophomonas *Species*

Armand Keating, MD
Professor of Medicine, University of Toronto, Toronto, Ontario, Canada
Hematopoietic Cell Transplantation

Robin K. Kelley, MD
Professor of Clinical Medicine, University of California, San Francisco School of Medicine, San Francisco, California
Liver and Biliary Tract Tumors

Richard B. Kennedy, PhD
Professor of Medicine and Co-Director, Vaccine Research Group, Mayo Clinic College of Medicine and Science, Rochester, Minnesota
Rubella (German Measles)

Fadlo R. Khuri, MD
President and Professor of Hematology and Medical Oncology, American University of Beirut; Adjunct Professor of Medicine, Pharmacology and Otolaryngology, Emory University School of Medicine, Atlanta, Georgia
Lung Cancer and Other Pulmonary Neoplasms

Rose Kim, MD
Associate Professor of Medicine, Cooper Medical School of Rowan University, Camden, New Jersey
Gram-Positive Rod Infections

Louis V. Kirchhoff, MD, MPH
Professor of Internal Medicine (Infectious Diseases), Psychiatry, and Epidemiology, University of Iowa Carver College of Medicine and College of Public Health, Iowa City, Iowa
Chagas Disease

Hannah Kirking, MD
Medical Epidemiologist, National Center for Immunization and Respiratory Diseases, US Centers for Disease Control and Prevention; Assistant Professor, Department of Medicine, Emory University, Atlanta, Georgia
Pre-2019 Coronaviruses

Ajay J. Kirtane, MD
Professor of Medicine, Columbia University Vagelos College of Physicians and Surgeons; Director, Cardiac Catheterization Laboratories, New York-Presbyterian/Columbia University Irving Medical Center, New York, New York
Interventional Diagnosis and Treatment of Coronary Artery Disease

Priya S. Kishnani, MD
Chen Family Distinguished Professor, Chief, Division of Medical Genetics, Department of Pediatrics, and Professor of Molecular Genetics and Microbiology, Duke University Medical Center, Durham, North Carolina
Glycogen Storage Diseases

Jeffrey D. Klausner, MD, MPH
Clinical Professor of Medicine and Population and Public Health Sciences, Keck School of Medicine of USC, Los Angeles, California
Neisseria gonorrhoeae *Infections*

Amy D. Klion, MD
Senior Clinical Investigator and Head of the Human Eosinophil Section, Deputy Chief of the Laboratory of Parasitic Diseases, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, Maryland
Eosinophilic Syndromes

Michael Klompas, MD, MPH
Professor of Medicine and Population Medicine, Department of Population Medicine, Harvard Medical School and Harvard Pilgrim Healthcare Institute; Hospital Epidemiologist, Brigham and Women's Hospital, Boston, Massachusetts
Overview of Pneumonia

David S. Knopman, MD
Robert H. and Susan M. Rewoldt Professorship in Neurology Honoring Bradley F. Boeve, M.D., Mayo Clinic College of Medicine and Science, Rochester, Minnesota
Regional Cerebral Dysfunction: Higher Mental Functions; Cognitive Impairment and Dementia

Christine J. Ko, MD
Professor of Dermatology and Pathology, Yale University School of Medicine, New Haven, Connecticut
Approach to Skin Diseases

Susheel Kodali, MD
Professor of Medicine, Columbia University Vagelos College of Physicians and Surgeons; Director, Structural Heart & Valve Center, New York-Presbyterian/Columbia University Medical Center, New York, New York
Valvular Heart Disease

Dimitrios P. Kontoyiannis, MD, ScD
Robert C. Hickey Chair in Clinical Care and Deputy Head, Division of Internal Medicine, The University of Texas MD Anderson Cancer Center, Houston, Texas
Mucormycosis; Mycetoma and Dematiaceous Fungal Infections

Barbara S. Koppel, MD
Professor of Clinical Neurology (Emeritus), New York Medical College, Valhalla, New York
Nutritional and Alcohol-Related Neurologic Disorders

Kevin M. Korenblat, MD
Professor of Medicine, Washington University School of Medicine in St. Louis, St. Louis, Missouri
Approach to the Patient with Jaundice or Abnormal Liver Tests

Bruce R. Korf, MD, PhD
Wayne H. and Sara Crews Finley Endowed Chair in Medical Genetics, Distinguished Professor of Genetics, and Associate Dean for Genomic Medicine, University of Alabama at Birmingham Heersink School of Medicine, Birmingham, Alabama
Principles of Genetics

Mark G. Kortepeter, MD, MPH
Professor of Preventive Medicine and Medicine and Vice President for Research, Uniformed Services University of the Health Sciences, Bethesda, Maryland
Bioterrorism

Anita A. Koshy, MD
Associate Professor of Neurology, University of Arizona, Tucson, Arizona
Toxoplasmosis

Shyamasundaran Kottilil, MD, PhD
Professor of Medicine and Chief of Infectious Diseases, University of Maryland School of Medicine, Baltimore, Maryland
Antiviral Therapy (Non-HIV)

Joseph A. Kovacs, MD
Senior Investigator, Critical Care Medicine Department, National Institutes of Health Clinical Center, Bethesda, Maryland
Pneumocystis *Pneumonia*

Thomas O. Kovacs, MD
Professor of Medicine, David Geffen School of Medicine at UCLA, Los Angeles, California
Gastrointestinal Hemorrhage

Kris V. Kowdley, MD
Professor of Medicine, Elson S. Floyd College of Medicine, and Director, Liver Institute Northwest, Washington State University, Seattle, Washington
Iron Overload (Hemochromatosis)

Monica Kraft, MD
Murray M. Rosenberg Professor and System Chair, Samuel Bronfman Department of Medicine, Icahn School of Medicine at Mount Sinai and Mount Sinai Health System, New York, New York
Approach to the Patient with Respiratory Disease

Christopher M. Kramer, MD
George A. Beller MD/Lantheus Medical Imaging Distinguished Professor of Cardiovascular Medicine and Chief, Cardiovascular Division, University of Virginia School of Medicine, Charlottesville, Virginia
Noninvasive Cardiac Imaging

Donna M. Krasnewich, MD, PhD
Program Director, National Institute of General Medical Sciences, National Institutes of Health, Bethesda, Maryland
Lysosomal Storage Diseases

William E. Kraus, MD
Richard and Pat Johnson Distinguished University Professor, Duke University School of Medicine, Durham, North Carolina
Physical Activity

Peter J. Krause, MD
Senior Research Scientist, Yale University School of Public Health and Yale University School of Medicine, New Haven, Connecticut
Babesiosis and Other Protozoan Diseases

Andrew T. Kroger, MD, MPH
Medical Officer, National Center for Immunization and Respiratory Diseases, Centers for Disease Control and Prevention, Atlanta, Georgia
Immunization

Daniela Kroshinsky, MD, MPH
Professor, Vice Chair of Strategic Initiatives and Faculty Development, and Director of Pediatric Dermatology, Department of Dermatology, Duke University School of Medicine, Durham, North Carolina
Macular, Papular, Purpuric, Vesiculobullous, and Pustular Diseases

John F. Kuemmerle, MD
Professor of Medicine, Virginia Commonwealth University School of Medicine, Richmond, Virginia
Inflammatory and Anatomic Diseases of the Intestine, Peritoneum, Mesentery, and Omentum

Ernst J. Kuipers, MD, PhD
Professor of Medicine, Erasmus MC University Medical Center, Rotterdam, Netherlands
Acid Peptic Disease

Jean S. Kutner, MD
Professor of Medicine, University of Colorado School of Medicine, Aurora, Colorado
Palliative Care

Daniel Laheru, MD
Ian T. MacMillan Professorship in Clinical Pancreatic Research, Johns Hopkins University School of Medicine, Baltimore, Maryland
Pancreatic Cancer

Rachel Lampert, MD
Professor of Medicine, Yale University School of Medicine, New Haven, Connecticut
Cardiac Arrest and Life-Threatening Arrhythmias

C. Seth Landefeld, MD
Professor and Chair of Medicine, University of Alabama at Birmingham Heersink School of Medicine, Birmingham, Alabama
Geriatric Assessment

Raphael J. Landovitz, MD, MSc
Professor of Medicine, Center for Clinical AIDS Research & Education, David Geffen School of Medicine at UCLA, Los Angeles, California
Prevention of Human Immunodeficiency Virus Infection

Donald W. Landry, MD, PhD
Hamilton Southworth Professor and Chair Emeritus, Department of Medicine, Columbia University Vagelos College of Physicians and Surgeons; Physician-in-Chief, Columbia University Irving Medical Center, New York, New York
Approach to the Patient with Renal Disease

Richard A. Lange, MD, MBA
Rick and Ginger Francis Endowed Professor and President, Texas Tech University Health Sciences Center El Paso; Dean, Paul L. Foster School of Medicine, El Paso, Texas
Acute Coronary Syndrome: Unstable Angina and Non–ST Elevation Myocardial Infarction

Hochang B. Lee, MD
John Romano Professor and Chair, Department of Psychiatry, University of Rochester School of Medicine & Dentistry, Rochester, New York
Psychiatric Disorders in Medical Practice

Nelson Lee, MD, MBBS
Professor, Institute for Pandemics, Dalla Lana School of Public Health, University of Toronto, Toronto, Ontario, Canada
Influenza

Andrew S. Levey, MD
Professor of Medicine and Dr. Gerald J and Dorothy R Friedman Professor Emeritus, Tufts University School of Medicine; Chief Emeritus, Division of Nephrology, Tufts Medical Center, Boston, Massachusetts
Chronic Kidney Disease

ALGrawany

Stephanie M. Levine, MD
Professor of Medicine, University of Texas Health San Antonio, San Antonio, Texas
Alveolar Filling Disorders

Gary R. Lichtenstein, MD
Professor of Medicine, University of Pennsylvania Perelman School of Medicine; Director, Center for Inflammatory Bowel Disease, Department of Medicine, Hospital of the University of Pennsylvania, Philadelphia, Pennsylvania
Inflammatory Bowel Disease

Jeffrey M. Liebmann, MD
Shirlee and Bernard Brown Professor and Vice Chair, Department of Ophthalmology, Columbia University Vagelos College of Physicians and Surgeons, New York, New York
Diseases of the Visual System

Jane M. Liebschutz, MD, MPH
Professor of Medicine, Falk Chair in Ambulatory Medicine, and Chief, Division of General Internal Medicine, University of Pittsburgh School of Medicine, UPMC Health System, Pittsburgh, Pennsylvania
Drug Use Disorders

Henry W. Lim, MD
Former Chair, Department of Dermatology; Senior Vice President for Academic Affairs, Henry Ford Health, Detroit, Michigan
Eczemas, Photodermatoses, Papulosquamous (Including Fungal) Diseases, and Figurate Erythemas

Aldo A.M. Lima, MD, PhD
Professor, Institute of Biomedicine, Federal University of Ceara, Fortaleza, Ceará, Brazil
Cryptosporidiosis

Ajit P. Limaye, MD
Professor of Medicine and Director, Solid Organ Transplant Infectious Disease Program, Departments of Medicine and Laboratory Medicine, Division of Allergy & Infectious Diseases, University of Washington, Seattle, Washington
Cytomegalovirus

Nita A. Limdi, PharmD, PhD, MSPH
Ray L Watts Heersink Endowed Chair and Professor, Departments of Neurology and of Epidemiology; Director, Translational Pharmacogenomics Program and Associate Director, Hugh Kaul Precision Medicine Institute, University of Alabama Birmingham Heersink School of Medicine, Birmingham, Alabama
Principles of Genetics

Mark S. Link, MD
Professor of Medicine, University of Texas Southwestern Medical Center, Dallas, Texas
Electrocardiography

Catherine Liu, MD
Professor, Vaccine and Infectious Disease Division, Fred Hutchinson Cancer Center; Professor of Medicine, University of Washington, Seattle, Washington
Staphylococcal Infections

Donald M. Lloyd-Jones, MD, ScM
Eileen M. Foell Professor of Heart Research; Professor of Preventive Medicine, Medicine, and Pediatrics; Chair, Department of Preventive Medicine; Northwestern University Feinberg School of Medicine, Chicago, Illinois
Epidemiology of Cardiovascular Disease

Fred A. Lopez, MD
Richard Vial Professor and Vice Chair, Department of Medicine, Louisiana State University Health Sciences Center-New Orleans, New Orleans, Louisiana
Tularemia and Other Francisella *Infections*

Arnold Louie, MD
Professor of Medicine, Molecular Genetics and Microbiology and Associate Director, Institute for Therapeutic Innovation, University of Florida College of Medicine, Orlando, Florida
Antibacterial Chemotherapy

Jeffrey M. Lyness, MD
President and CEO, American Board of Psychiatry & Neurology, Deerfield, Illinois; Professor Emeritus of Psychiatry, University of Rochester School of Medicine & Dentistry, Rochester, New York
Psychiatric Disorders in Medical Practice

C. Ronald MacKenzie, MD
C. Ronald MacKenzie Chair in Ethics and Medicine, Hospital for Special Surgery; Professor of Clinical Medicine and Medical Ethics, Weill Medical College of Cornell University, New York, New York
Surgical Treatment of Joint Diseases

Calman A. MacLennan, BM, BCh, DPhil
Senior Program Officer—Bacterial Vaccines, Enteric and Diarrheal Diseases, Global Health, Bill & Melinda Gates Foundation, Seattle, Washington; Jenner Investigator, Jenner Institute, Nuffield Department of Medicine, University of Oxford, Oxford, Oxfordshire, United Kingdom; Professor of Vaccine Immunology and Director of BactiVac, Institute of Immunology and Immunotherapy, University of Birmingham, Birmingham, West Midlands, United Kingdom
Shigellosis

Harriet L. MacMillan, CM, MD, MSc
Chedoke Health Chair in Child Psychiatry and Distinguished University Professor of Psychiatry & Behavioural Neurosciences and of Pediatrics, Offord Centre for Child Studies, McMaster University Michael G. DeGroote School of Medicine, Hamilton, Ontario, Canada
Intimate Partner Violence

Robert D. Madoff, MD
Professor of Surgery, University of Minnesota, Minneapolis, Minnesota
Diseases of the Rectum and Anus

Jacquelyn Maher, MD
William and Mary Ann Rice Distinguished Professor of Medicine and Director of UCSF Liver Center, University of California, San Francisco School of Medicine, San Francisco, California
Alcoholic and Nonalcoholic Steatohepatitis

Lisa A. Maier, MD, MSPH
Professor of Medicine, University of Colorado, and Chief, Division of Occupational Environmental Health Sciences, National Jewish Health, Denver, Colorado
Physical and Chemical Injuries of the Lung

Frank Maldarelli, MD, PhD
Head, Clinical Retrovirology Section, HIV Dynamics and Replication Program, NCI-Frederick, Frederick, Maryland
Pathobiology of Human Immunodeficiency Viruses

Atul Malhotra, MD
Peter C Farrell Presidential Chair and Professor of Medicine, Research Chief of Pulmonary and Critical Care Medicine, and Director of Sleep Medicine, University of California, San Diego, School of Medicine, La Jolla, California
Disorders of Ventilatory Control

Mark J. Manary, MD
Helene B. Roberson Professor of Pediatrics, Washington University, St. Louis, Missouri
Severe Malnutrition

Luis A. Marcos, MD, MPH
Associate Professor of Medicine and Director of the Tick-Borne Disease Center, Division of Infectious Diseases, Department of Medicine; Department of Microbiology and Immunology, Renaissance School of Medicine at Stony Brook University, Stony Brook, New York
Trematode Infections

Ariane J. Marelli, MD, MPH
Professor of Medicine, McGill University Faculty for Medicine and Health Sciences, Director, McGill Adult Unit for Congenital Heart Disease, McGill University Health Centre, Montreal, Quebec, Canada
Congenital Heart Disease in Adults

Andrew R. Marks, MD
Wu Professor and Chair, Department of Physiology and Cellular Biophysics, Director, Helen and Clyde Wu Center for Molecular Cardiology, Columbia University Vagelos College of Physicians and Surgeons, New York, New York
Cardiac and Circulatory Function

Jonas Marschall, MD, MSc, DTM&H
Professor of Medicine, Washington University School of Medicine in St. Louis, St. Louis, Missouri
Legionella *Infections*

Paul Martin, MD
Mandel Chair in Gastroenterology and Chief, Division of Digestive Health and Liver Diseases, University of Miami Miller School of Medicine, Miami, Florida
Approach to the Patient with Liver Disease

Fernando J. Martinez, MD, MS
Bruce Webster Professor of Internal Medicine, Weill Medical College of Cornell University; Chief, Division of Pulmonary and Critical Care Medicine, Weill Medical College of Cornell University/NY Presbyterian Hospital, New York, New York
Interstitial Lung Disease

Joel B. Mason, MD
Professor of Medicine and Nutrition, Divisions of Gastroenterology and Clinical Nutrition, Tufts University; Director, Vitamins & Carcinogenesis Laboratory, U.S.D.A. Human Nutrition Research Center at Tufts University, Boston, Massachusetts
Vitamins, Trace Minerals, and Other Micronutrients

Henry Masur, MD
Chief, Critical Care Medicine Department, Clinical Center, National Institutes of Health, Bethesda, Maryland
Microbial Complications of HIV/AIDS

Amy J. Mathers, MD
Associate Professor of Medicine and Pathology, Associate Director of Clinical Microbiology, and Medical Director Antimicrobial Stewardship, University of Virginia School of Medicine, Charlottesville, Virginia
Enterobacterales: Non-Enteric Infections and Multidrug Resistance

Michael A. Matthay, MD
Professor of Medicine and Anesthesia, University of California, San Francisco School of Medicine, San Francisco, California
Acute Respiratory Failure

F. Dennis McCool, MD
Professor of Medicine, Warren Alpert Medical School of Brown University, Providence, Rhode Island
Diseases of the Diaphragm, Chest Wall, Pleura, and Mediastinum

Iain B. McInnes, PhD
Vice-Principal and Head of College of Medical, Veterinary and Life Sciences, Muirhead Chair of Medicine/Versus Arthritis Professor of Rheumatology, University of Glasgow, Glasgow, United Kingdom
Rheumatoid Arthritis

Vallerie McLaughlin, MD
Kim A. Eagle MD Endowed Professor of Cardiovascular Medicine, Professor of Medicine, and Director, Pulmonary Hypertension Program, University of Michigan Medical School, Ann Arbor, Michigan
Pulmonary Hypertension

Amy McMichael, MD
Professor of Dermatology, Wake Forest School of Medicine, Winston-Salem, North Carolina
Infections, Pigmentation Disorders, Regional Dermatology, and Distinctive Lesions in Black Skin

John J.V. McMurray, MB ChB, MD
Professor of Medical Cardiology, British Heart Foundation Cardiovascular Research Centre, University of Glasgow; Honorary Consultant Cardiologist, Queen Elizabeth University Hospital Glasgow, Glasgow, Scotland, United Kingdom
Heart Failure: Treatment and Prognosis

Kenneth R. McQuaid, MD
Professor of Clinical Medicine and Vice-Chair, Department of Medicine, University of California, San Francisco School of Medicine; Chief of the Medical Service, San Francisco Veterans Affairs Medical Center, San Francisco, California
Approach to the Patient with Gastrointestinal Disease

Paul S. Mead, MD, MPH
Chief, Bacterial Diseases Branch, Division of Vector-Borne Diseases, Centers for Disease Control and Prevention, Fort Collins, Colorado
Plague and Other Yersinia *Infections*

Robert T. Means, Jr., MD
Professor of Internal Medicine and Clinical Professor of Pathology, East Tennessee State University James H. Quillen College of Medicine, Johnson City, Tennessee
Approach to the Anemias

Michael T. Melia, MD
Associate Professor of Medicine, Johns Hopkins University School of Medicine, Baltimore, Maryland
Approach to Fever or Suspected Infection in the Normal Host

Ingo K. Mellinghoff, MD
Chair, Department of Neurology, Memorial Sloan Kettering Cancer Center; Professor of Neurology and of Neuroscience, Weill Medical College of Cornell University, New York, New York
Tumors of the Central Nervous System

Genevieve B. Melton, MD, PhD
Professor of Surgery, University of Minnesota Medical School, Minneapolis, Minnesota
Diseases of the Rectum and Anus

Samuel T. Merrick, MD
Professor of Clinical Medicine, Weill Medical College of Cornell University, New York, New York
Systemic Manifestations of HIV/AIDS

Marisa H. Miceli, MD
Clinical Professor of Infectious Diseases and Internal Medicine, University of Michigan Medical School, Ann Arbor, Michigan
Endemic Mycoses

Marc Michel, MD, MSc
Professor and Head of the Department of Internal Medicine and Clinical Immunology, Henri Mondor University Hospital, Assistance Publique Hopitaux de Paris, Université Paris-Est Créteil, Creteil, France
Autoimmune and Intravascular Hemolytic Anemias

Ali H. Mokdad, PhD
Chief Strategy Officer, Population Health, and Professor of Health Metrics Sciences, Department of Health Metrics Sciences, Institute of Health Metrics and Evaluation, University of Washington, Seattle, Washington
Global Health

Ernest Moy, MD, MPH
Executive Director, Office of Health Equity, Veterans Health Administration, Washington D.C.
Measuring Health and Health Care

Debabrata Mukherjee, MD, MS
Professor and Chairman, Department of Internal Medicine, Texas Tech University Health Sciences Center El Paso, El Paso, Texas
Acute Coronary Syndrome: Unstable Angina and Non–ST Elevation Myocardial Infarction

Andrew H. Murr, MD
Professor and Chairman, Department of Otolaryngology-Head and Neck Surgery, University of California, San Francisco School of Medicine, San Francisco, California
Approach to the Patient with Nose, Sinus, and Ear Disorders

Robert J. Myerburg, MD
Professor of Medicine, Cardiovascular Genetics, and Physiology, Department of Medicine, University of Miami Miller School of Medicine, Miami, Florida
Cardiac Arrest and Life-Threatening Arrhythmias

Kari C. Nadeau, MD, PhD
John Rock Professor of Climate and Population Studies and Chair, Department of Environmental Health, Harvard T.H. Chan School of Public Health, Boston, Massachusetts
Approach to the Patient with Allergic or Immunologic Disease

A L G r a w a n y

Avindra Nath, MD
Chief, Section of Infections of the Nervous System, National Institutes of Neurological Diseases and Stroke, National Institutes of Health, Bethesda, Maryland
Meningitis: Bacterial, Viral, and Other; Brain Abscess and Parameningeal Infections

Genevieve Neal-Perry, MD, PhD
Robert A. Ross Distinguished Professor and Chair, Department of Obstetrics and Gynecology, University of North Carolina School of Medicine, Chapel Hill, North Carolina
Menopause

Eric G. Neilson, MD
Vice President for Medical Affairs, Lewis Landsberg Dean, and Professor of Medicine and of Cell and Developmental Biology, Northwestern University Feinberg School of Medicine, Chicago, Illinois
Interstitial Nephritis

Christina A. Nelson, MD, MPH
Medical Officer, Bacterial Diseases Branch, Division of Vector-Borne Diseases, Centers for Disease Control and Prevention, Fort Collins, Colorado
Plague and Other Yersinia *Infections*

David B. Nelson, MD, FACOG
Gillette Professorship of Obstetrics and Gynecology, Dedman Family Scholar in Clinical Care, Associate Professor of Obstetrics and Gynecology and Chief, Division of Maternal-Fetal Medicine, University of Texas Southwestern Medical Center, Dallas, Texas
Medical Issues in Pregnancy

Lewis S. Nelson, MBA, MD
Professor and Chair, Department of Emergency Medicine; Director, Division of Medical Toxicology, Rutgers New Jersey Medical School, Newark, New Jersey
Acute Poisoning

Eric J. Nestler, MD, PhD
Nash Family Professor of Neuroscience and Director, Friedman Brain Institute, Icahn School of Medicine at Mount Sinai, New York, New York
Biology of Addiction

Kathleen M. Neuzil, MD, MPH
Myron M. Levine Professor of Medicine and Pediatrics and Director, Center for Vaccine Development and Global Health, University of Maryland School of Medicine, Baltimore, Maryland
COVID-19 Treatment and Vaccination

Lynnette K. Nieman, MD
Senior Investigator, Diabetes, Endocrinology and Obesity Branch, National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health, Bethesda, Maryland
Approach to the Patient with Endocrine Disease; Adrenal Cortex; Polyglandular Disorders

Alexander S. Niven, MD
Professor of Medicine, Mayo Clinic College of Medicine and Science, Rochester, Minnesota
Respiratory Testing and Function

Christopher M. O'Connor, MD
Adjunct Professor of Medicine, Duke University School of Medicine, Durham, North Carolina; CEO, Inova Heart and Vascular Institute, Fairfax, Virginia
Heart Failure: Epidemiology, Pathobiology, and Diagnosis

Francis G. O'Connor, MD, MPH
Professor of Military and Emergency Medicine and Medical Director, Consortium for Health and Military Performance, Uniformed Services University of the Health Sciences, Bethesda, Maryland
Disorders Due to Heat and Cold; Rhabdomyolysis

Patrick G. O'Connor, MD, MPH
Dan Adams and Amanda Adams Professor of Medicine and Chief, General Internal Medicine, Yale University School of Medicine, New Haven, Connecticut
Alcohol Use Disorders

Anne E. O'Donnell, MD
The Nehemiah and Naomi Cohen Chair in Pulmonary Disease Research, Georgetown University School of Medicine; Chief, Division of Pulmonary, Critical Care and Sleep Medicine, Georgetown University Medical Center, Washington, D.C.
Bronchiectasis, Atelectasis, Cavitary, or Cystic Lung Diseases

James S. O'Donnell, MD, PhD
Professor, Irish Centre for Vascular Biology, Royal College of Surgeons in Ireland, Dublin, Ireland
Von Willebrand Disease and Hemorrhagic Abnormalities of Platelet and Vascular Function

Jae K. Oh, MD
Professor of Medicine, Mayo Clinic College of Medicine and Science, Rochester, Minnesota; Director, Heart Vascular Stroke Institute, Samsung Medical Center, Seoul, Gangnam, South Korea
Pericardial Diseases

Michael S. Okun, MD
Professor and Chair of Neurology, Fixel Institute for Neurological Diseases, University of Florida College of Medicine, Gainesville, Florida
Parkinsonism; Other Movement Disorders

Sean T. O'Leary, MD, MPH
Professor of Pediatrics, University of Colorado School of Medicine, Aurora, Colorado
Papillomavirus

Jeffrey E. Olgin, MD
Gallo-Chatterjee Distinguished Professor and Chief of Cardiology, University of California, San Francisco School of Medicine, San Francisco, California
Approach to the Patient with Suspected Arrhythmia

Kenneth N. Olivier, MD, MPH
Professor of Medicine, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina
The Nontuberculous Mycobacteria

Iacopo Olivotto, MD
Professor of Cardiovascular Medicine, Meyer Children's Hospital IRCCS, University of Florence, Florence, Italy
Diseases of the Myocardium and Endocardium

Nancy J. Olsen, MD
Professor of Medicine, Penn State Milton S. Hershey Medical Center, Hershey, Pennsylvania
Biologic Agents and Signaling Inhibitors

Walter A. Orenstein, MD, DSc
Professor of Medicine, Pediatrics, Epidemiology & Global Health, Emory University School of Medicine; Associate Director, Emory Vaccine Center, Atlanta, Georgia
Immunization

Thomas L. Ortel, MD, PhD
Professor of Medicine and Pathology and Chief, Division of Hematology, Duke University School of Medicine, Durham, North Carolina
Antithrombotic and Antiplatelet Therapy

John J. O'Shea, MD
Scientific Director, National Institute of Arthritis and Musculoskeletal and Skin Diseases, National Institutes of Health, Bethesda, Maryland
Biologic Agents and Signaling Inhibitors

Douglas R. Osmon, MD
Professor of Medicine, Mayo Clinic College of Medicine and Science, Rochester, Minnesota
Infections of Bursae, Joints, and Bones

Jill L. Ostrem, MD
Carlin and Ellen Wiegner Distinguished Professor of Neurology, University of California, San Francisco School of Medicine, San Francisco, California
Parkinsonism; Other Movement Disorders

Luis Ostrosky-Zeichner, MD
Professor and Division Chief, Division of Infectious Diseases, University of Texas Health Science Center at Houston; Medical Director for Epidemiology, Memorial Hermann Texas Medical Center, Houston, Texas
Mucormycosis

Catherine M. Otto, MD
J. Ward Kennedy-Hamilton Endowed Chair in Cardiology and Professor of Medicine, University of Washington School of Medicine; Director, Heart Valve Clinic, and Associate Director, Echocardiography, University of Washington Medical Center, Seattle, Washington
Echocardiography

Martin G. Ottolini, MD
Professor of Pediatrics and Director, Capstone Student Research Program, Office of the Dean, School of Medicine, Uniformed Services University of the Health Sciences, Bethesda, Maryland
Measles

Inna G. Ovsyannikova, PhD
Professor of Medicine, Mayo Clinic College of Medicine and Science, Rochester, Minnesota
Rubella (German Measles)

Peter G. Pappas, MD
Professor of Medicine, University of Alabama at Birmingham Heersink School of Medicine, Birmingham, Alabama
Candidiasis; Mycetoma and Dematiaceous Fungal Infections

Ben Ho Park, MD, PhD
Benjamin F. Byrd, Jr Chair in Oncology and Professor of Medicine, Vanderbilt University School of Medicine; Director, Vanderbilt-Ingram Cancer Center, Vanderbilt University Medical Center, Nashville, Tennessee
Cancer Biology and Genetics

Robin Patel, MD
Elizabeth P. and Robert E. Allen Professor of Individualized Medicine and Professor of Medicine and of Microbiology; Director, Infectious Diseases Research Laboratory and Vice Chair Education, Department of Laboratory Medicine and Pathology, Mayo Clinic College of Medicine and Science, Rochester, Minnesota
Introduction to Microbial Disease: Pathophysiology and Diagnostics

Thomas F. Patterson, MD
Professor of Medicine, Long School of Medicine, University of Texas Health Science Center, San Antonio; Chief, Infectious Diseases, UT Health San Antonio, San Antonio, Texas
Aspergillosis

Jean-Michel Pawlotsky, MD, PhD
Professor, Department of Virology, Henri Mondor University Hospital AP-HP, Paris-Est University & INSERM U955, Créteil, France
Acute Viral Hepatitis; Chronic Viral and Autoimmune Hepatitis

Thomas H. Payne, MD
Professor of Medicine and Professor of Biomedical Informatics and Medical Education, University of Washington School of Medicine; Adjunct Professor of Health Systems and Population Health, University of Washington School of Public Health, Seattle, Washington
Statistical Interpretation of Data for Clinical Decision Making

Elizabeth N. Pearce, MD, MSc
Professor of Medicine, Boston University Chobanian & Avedisian School of Medicine, Boston, Massachusetts
Thyroid

Richard D. Pearson, MD
Professor Emeritus of Medicine, University of Virginia School of Medicine, Charlottesville, Virginia
Antiparasitic Therapy

Trish M. Perl, MD, MSc
Professor of Medicine and H. Ben and Isabelle T. Decherd Chair in Internal Medicine in Honor of Henry M. Winans, Sr., M.D., University of Texas Southwestern Medical Center, Dallas, Texas
Enterococcal Infections

Brett W. Petersen, MD, MPH
Deputy Branch Chief, Poxvirus and Rabies Branch, Centers for Disease Control and Prevention, Atlanta, Georgia
Smallpox, Monkeypox, and Other Poxvirus Infections

William A. Petri, Jr., MD, PhD
Wade Hampton Frost Professor of Epidemiology and Vice Chair for Research, Department of Medicine, University of Virginia School of Medicine, Charlottesville, Virginia
Relapsing Fever and Other Borrelia *Infections; African Sleeping Sickness; Amebiasis*

Marc A. Pfeffer, MD, PhD
Distinguished Dzau Professor of Medicine, Harvard Medical School; Senior Physician, Brigham and Women's Hospital, Boston, Massachusetts
Heart Failure: Treatment and Prognosis

Jennifer A. Philips, MD, PhD
Theodore and Bertha Bryan Professor of Medicine and Molecular Microbiology and Co-Director, Division of Infectious Diseases, Washington University School of Medicine in St. Louis, St. Louis, Missouri
Tuberculosis

David S. Pisetsky, MD, PhD
Professor of Medicine and Immunology, Duke University School of Medicine; Medical Research Service, VA Medical Center, Durham, North Carolina
Laboratory Testing in the Rheumatic Diseases

Steven D. Pletcher, MD
Professor of Clinical Otolaryngology, University of California, San Francisco School of Medicine, San Francisco, California
Approach to the Patient with Nose, Sinus, and Ear Disorders

Ian D. Plumb, MBBS, MSc
Epidemiologist, National Center for Immunization and Respiratory Diseases, Centers for Disease Control and Prevention, Atlanta, Georgia
Pre-2019 Coronaviruses

Gregory A. Poland, MD
Lowell Leary Emeritus Mary Professor of Medicine and Director, Vaccine Research Group, Mayo Clinic College of Medicine and Science, Rochester, Minnesota
Rubella (German Measles)

Frank Powell, PhD
Professor of Medicine, University of California, San Diego School of Medicine, La Jolla, California
Disorders of Ventilatory Control

Reed E. Pyeritz, MD, PhD
William Smilow Professor of Medicine and Genetics, Emeritus, University of Pennsylvania Perelman School of Medicine, Philadelphia, Pennsylvania
Inherited Diseases of Connective Tissue

Thomas C. Quinn, MD, MSc
Professor of Medicine and Pathology and Director, Center for Global Health, Johns Hopkins University School of Medicine; Associate Director for International Research, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Baltimore, Maryland
Epidemiology and Diagnosis of Human Immunodeficiency Virus Infection and Acquired Immunodeficiency Syndrome; Acute Clinical Manifestations and Diagnosis of HIV

Vincent Racaniello, PhD
Higgins Professor of Microbiology & Immunology, Columbia University Vagelos College of Physicians and Surgeons, New York, New York
COVID-19: Virology and Pathology

Jai Radhakrishnan, MD, MS
Professor of Medicine, Columbia University Vagelos College of Physicians and Surgeons; Clinical Director, Division of Nephrology, Columbia University Irving Medical Center, New York, New York
Disorders of Sodium and Water; Glomerular Disorders and Nephrotic Syndromes

Jerald Radich, MD
Professor of Medical Oncology, Clinical Research Division, Fred Hutchinson Cancer Center and University of Washington School of Medicine, Seattle, Washington
Chronic Myeloid Leukemia

Petros I. Rafailidis, MD, PhD, MSc
Associate Professor Internal Medicine-Infectious Diseases, Democritus University of Thrace; Second University Department of Internal Medicine, University General Hospital of Greece, Alexandroupolis, Greece; Senior Researcher, Alfa Institute of Biomedical Sciences, Athens, Greece
Pseudomonas *and* Burkholderia *Infections*

Ganesh Raghu, MD
Professor of Medicine and Laboratory Medicine (adjunct), University of Washington School of Medicine; Director, Center for Interstitial Lung Diseases, and Co-Director, Scleroderma Clinic, University of Washington Medical Center, Seattle, Washington
Interstitial Lung Disease

Margaret V. Ragni, MD, MPH
Professor of Medicine and Clinical Translational Science, University of Pittsburgh School of Medicine; Director, Hemophilia Center of Western Pennsylvania, Pittsburgh, Pennsylvania
Coagulation Factor Deficiencies

Proton Rahman, MD
University Research Professor of Medicine, Memorial University, St. Johns, Newfoundland, Canada
Spondyloarthritis

S. Vincent Rajkumar, MD
Edward W. and Betty Knight Scripps Professor of Medicine, Mayo Clinic College of Medicine and Science, Rochester, Minnesota
Plasma Cell Disorders

Stuart H. Ralston, MB ChB, MD
Versus Arthritis Professor of Rheumatology, University of Edinburgh, Edinburgh, United Kingdom
Paget Disease of Bone

Didier Raoult, MD, PhD
Emeritus Professor, Aix-Marseille Université and, Institut Hospitalo-Universitaire Méditerranée-Infection, Marseille, France
Bartonella *Infections; Rickettsial Infections*

Annette C. Reboli, MD
Dean and Professor of Medicine, Cooper Medical School of Rowan University, Camden, New Jersey
Gram-Positive Rod Infections

K. Rajender Reddy, MD
Founders Professor of Medicine, University of Pennsylvania Perelman School of Medicine, Philadelphia, Pennsylvania
Bacterial, Parasitic, Fungal, and Granulomatous Liver Diseases

Donald A. Redelmeier, MD
Professor of Medicine, University of Toronto; Canada Research Chair, Medical Decision Science; Senior Scientist, Evaluative Clinical Sciences, Sunnybrook Research Institute; Staff Physician, Sunnybrook Health Sciences Centre, Toronto, Ontario, Canada
Postoperative Care and Complications

Carrie A. Redlich, MD, MPH
Professor of Medicine, Pulmonary and Critical Care Medicine, Yale University School of Medicine, New Haven, Connecticut
Occupational Lung Disease

John Reilly, MD
Richard D. Krugman Endowed Chair, Dean, School of Medicine, and Vice Chancellor for Health Affairs, University of Colorado School of Medicine, Aurora, Colorado
Chronic Obstructive Pulmonary Disease

Megan E. Reller, MD, PhD, MPH
Associate Professor of Medicine, Duke University School of Medicine, Durham, North Carolina
Zoonoses

Hilary E.L. Reno, MD, PhD
Professor of Medicine, Washington University in St. Louis, St. Louis, Missouri
Diseases Caused by Chlamydiae

Neil M. Resnick, MD
Thomas Detre Professor of Medicine, University of Pittsburgh School of Medicine; Chief, Division of Geriatric Medicine and Gerontology, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania
Urinary Incontinence

Louis B. Rice, MD
Joukowsky Family Professor and Chair of Medicine, Professor of Molecular Microbiology and Immunology, Warren Alpert Medical School of Brown University, Providence, Rhode Island
Principles of Anti-Infective Therapy

E. Steve Roach, MD
Professor of Neurology, University of Texas Dell Medical School, Dell Children's Hospital, Austin, Texas
Developmental and Neurocutaneous Disorders

Jennifer G. Robinson, MD, MPH
Professor Emeritus of Epidemiology and Medicine; Director, Prevention Intervention Center, Department of Epidemiology, University of Iowa Carver College of Medicine, Iowa City, Iowa
Disorders of Lipid Metabolism

Inez Rogatsky, PhD
Professor of Microbiology and Immunology, Weill Medical College of Cornell University; Senior Scientist, Arthritis and Tissue Degeneration Program, Hospital for Special Surgery, New York, New York
Immunomodulatory Drugs

Joseph G. Rogers, MD
Adjunct Professor of Medicine, Duke University School of Medicine, Durham, North Carolina; President and CEO, Texas Heart Institute, Houston, Texas
Heart Failure: Epidemiology, Pathobiology, and Diagnosis

Jean-Marc Rolain, PharmD, PhD
Professor, Aix-Marseille Université and Institut Hospitalo-Universitaire Méditerranée Infection, Marseille, France
Bartonella *Infections*

Barrett J. Rollins, MD, PhD
Linde Family Professor of Medicine, Dana-Farber Cancer Institute, Brigham and Women's Hospital, and Harvard Medical School, Boston, Massachusetts
Histiocytoses

José R. Romero, MD
Arkansas Secretary of Health and Director of the Department of Health; Professor of Pediatrics, University of Arkansas for Medical Sciences, Little Rock, Arkansas
Enteroviruses

Jennifer B. Rosen, MD
Director, Epidemiology and Surveillance, Bureau of Immunization, New York City Department of Health and Mental Hygiene, Long Island City, New York
Mumps

Philip J. Rosenthal, MD
Professor of Medicine, University of California, San Francisco School of Medicine, San Francisco, California
Malaria

James A. Russell, MD
Professor of Medicine, University of British Columbia, Vancouver, British Columbia, Canada
Shock Syndromes Related to Sepsis

Anil K. Rustgi, MD
Herbert and Florence Irving Professor of Medicine and Director, Herbert Irving Comprehensive Cancer Center, Columbia University Vagelos College of Physicians and Surgeons; Chief, New York-Presbyterian Hospital/Columbia University Irving Medical Center Cancer Service, New York, New York
Approach to Medicine, the Patient, and the Medical Profession: Medicine as a Learned and Humane Profession; Neoplasms of the Esophagus and Stomach

Joshua D. Safer, MD
Professor of Medicine, Icahn School of Medicine at Mount Sinai, and Executive Director, Center for Transgender Medicine and Surgery, Mount Sinai Health System, New York, New York
Transgender Medicine

Sarbjit S. Saini, MD
Professor of Medicine, Johns Hopkins University School of Medicine, Baltimore, Maryland
Urticaria and Angioedema

Jane E. Salmon, MD
Collette Kean Research Chair, Hospital for Special Surgery; Professor of Medicine, Weill Medical College of Cornell University, New York, New York
Tissue Injury and Repair

Edsel Maurice T. Salvana, MD, DTM&H
Director, Institute of Molecular Biology and Biotechnology, National Institutes of Health, University of the Philippines Manila; Professor, Section of Infectious Diseases, Department of Medicine, Philippine General Hospital, Manila, Philippines
Brucellosis

ALGrawany

Nanette Santoro, MD
Professor and E. Stewart Taylor Chair, Department of Obstetrics and Gynecology, University of Colorado School of Medicine, Aurora, Colorado
Menopause

Peter A. Santucci, MD
Professor of Medicine, Loyola University Medical Center, Maywood, Illinois
Electrophysiologic Procedures and Surgery

Mark J. Sarnak, MD, MS
Dr. Gerald J and Dorothy R Friedman Professor of Medicine and Chief, Division of Nephrology, Tufts University School of Medicine, Boston, Massachusetts
Chronic Kidney Disease

Kerry J. Savage, MD
Professor of Medicine, University of British Columbia; Medical Oncologist, British Columbia Cancer Agency, Vancouver, British Columbia, Canada
Hodgkin Lymphoma

Patrice Savard, MD, MSc
Associate Clinical Professor of Microbiology, Infectious Diseases and Immunology, Université de Montréal; Chief, Infectious Diseases Division, Centre Hospitalier de l'Université de Montréal (CHUM), Québec, Canada
Enterococcal Infections

Michael N. Sawka, PhD
Adjunct Professor, School of Biological Sciences, Georgia Institute of Technology, Atlanta, Georgia
Disorders Due to Heat and Cold

Paul D. Scanlon, MD
Professor of Medicine, Mayo Clinic College of Medicine and Science, Rochester, Minnesota
Respiratory Testing and Function

Andrew I. Schafer, MD
Professor of Medicine and Director, Richard T. Silver Center for Myeloproliferative Neoplasms, Weill Medical College of Cornell University, New York, New York
Thrombotic Disorders: Hypercoagulable States; Approach to the Patient with Bleeding or Thrombosis; Disseminated Intravascular Coagulation and Bleeding in Liver Failure

Manuel Schiff, MD, PhD
Professor of Paediatrics, Reference Center for Inborn Errors of Metabolism, Necker University Hospital, APHP and University of Paris Cité; INSERM UMRS_1163, Institut Imagine, Paris, France
Homocystinuria and Hyperhomocysteinemia

Michael L. Schilsky, MD
Professor of Medicine and Surgery, Yale University School of Medicine, New Haven, Connecticut
Wilson Disease

Thomas Rudolf Schneider, MD, PhD
Professor of Infectious Diseases, Medical Clinic 1, Department of Gastroenterology, Infectious Diseases and Rheumatology, Charite Campus Benjamin Franklin, Berlin, Germany
Whipple Disease

Robert T. Schooley, MD
Professor of Medicine, University of California, San Diego School of Medicine, San Diego, California
Epstein-Barr Virus Infection

David L. Schriger, MD, MPH
Professor Emeritus and Vice Chair of Emergency Medicine, David Geffen School of Medicine at UCLA, Los Angeles, California
Approach to the Patient with Abnormal Vital Signs

Lynn M. Schuchter, MD
Madlyn and Leonard Abramson Professor of Medicine and Director, Tara Miller Melanoma Center, University of Pennsylvania Perelman School of Medicine, Philadelphia, Pennsylvania
Melanoma and Nonmelanoma Skin Cancers

Lawrence B. Schwartz, MD, PhD
Distinguished Professor of Medicine, Virginia Commonwealth University School of Medicine, Richmond, Virginia
Anaphylaxis

Carlos Seas, MD, MSc
Associate Professor of Medicine, Universidad Peruana Cayetano Heredia; Vice Director, Alexander von Humboldt Tropical Medicine Institute, and Attending Physician, Infectious and Tropical Medicine, Hospital Nacional Cayetano Heredia, Lima, Peru
Cholera and Other Vibrio *Infections*

Steven A. Seifert, MD[†]
Professor of Emergency Medicine, University of New Mexico School of Medicine; Medical Director, New Mexico Poison and Drug Information Center, Albuquerque, New Mexico
Envenomation, Bites, and Stings

Julian Lawrence Seifter, MD
James G. Haidas Distinguished Chair in Medicine, Brigham and Women's Hospital and Harvard Medical School, Boston, Massachusetts
Potassium Disorders; Acid-Base Disorders

Duygu Selcen, MD
Professor of Neurology and Pediatrics, Mayo Clinic College of Medicine and Science, Rochester, Minnesota
Muscle Diseases

Magdy Selim, MD, PhD
Professor of Neurology, Harvard Medical School, and Chief, Division of Stroke and Cerebrovascular Disease, Beth Israel Hospital, Boston, Massachusetts
Hemorrhagic Cerebrovascular Disease

Carol E. Semrad, MD
Professor of Medicine, University of Chicago Pritzker School of Medicine, Chicago, Illinois
Approach to the Patient with Diarrhea and Malabsorption

Jorge Sepulveda, MD, PhD
Professor of Pathology, George Washington University School of Medicine and Health Sciences, Washington, D.C.
Reference Intervals and Laboratory Values

Pamela J. Shaw, DBE, MBBS, MD
Professor of Neurology, Sheffield Institute for Translational Neuroscience, University of Sheffield, Sheffield, United Kingdom
Amyotrophic Lateral Sclerosis and Other Motor Neuron Diseases

Beth H. Shaz, MD
Professor of Pathology and Deputy Director, Marcus Center for Cellular Cures, Duke University School of Medicine, Durham, North Carolina
Transfusion Medicine

Robert L. Sheridan, MD
Professor of Surgery, Harvard Medical School and Massachusetts General Hospital, Boston, Massachusetts
Medical Aspects of Trauma and Burns

Stuart Sherman, MD
Glen A. Lehman Professor of Gastroenterology, Professor of Medicine and of Radiology, and Director, Advanced Endoscopy, Indiana University School of Medicine, Indianapolis, Indiana
Diseases of the Gallbladder and Bile Ducts

Kaveh G. Shojania, MD
Professor and Vice Chair (Quality & Innovation), Department of Medicine, University of Toronto, Toronto, Ontario, Canada
Quality, Safety, and Value

Bo Shopsin, MD, PhD
Associate Professor, Department of Medicine and Microbiology, New York University Grossman School of Medicine, New York, New York
Staphylococcal Infections

Michael E. Shy, MD
Carver College of Medicine Chair in Inherited Neuropathies and Professor of Neurology, Pediatrics, and Molecular Physiology and Biophysics, University of Iowa Carver College of Medicine, Iowa City, Iowa
Peripheral Neuropathies

[†]Deceased.

Ellen Sidransky, MD
Chief, Medical Genetics Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, Maryland
Lysosomal Storage Diseases

Costi D. Sifri, MD
Professor of Medicine and Medical Director, Immunocompromised Infectious Diseases Program, University of Virginia School of Medicine, Charlottesville, Virginia
Approach to Fever and Suspected Infection in the Immunocompromised Host

Robert F. Siliciano, MD, PhD
Professor of Medicine, Johns Hopkins University School of Medicine; Investigator, Howard Hughes Medical Institute, Baltimore, Maryland
Pathobiology of Human Immunodeficiency Viruses

David L. Simel, MD, MHS
Professor of Medicine, Duke University School of Medicine; Chief, Medical Service, Durham Veterans Affairs Medical Center, Durham, North Carolina
History and Physical Examination

Karl Skorecki, MD
Professor, Azrieli Faculty of Medicine, Bar-Ilan University, Safed Gan, Israel
Regenerative Medicine, Cell Therapy, and Gene Therapy

Barbara A. Slawski, MD, MS
Professor of Medicine and Chief of Hospital Medicine, Medical College of Wisconsin, Milwaukee, Wisconsin
Principles of Medical Consultation

Arthur S. Slutsky, CM, MD
Professor of Medicine, Surgery and Biomedical Engineering, University of Toronto; St Michael's Hospital; Keenan Research Centre, Li Ka Shing Knowledge Institute, Unity Health Toronto, Toronto, Ontario, Canada
Mechanical Ventilation

Gerald W. Smetana, MD
Professor of Medicine, Harvard Medical School and Physician, Division of General Medicine, Beth Israel Deaconess Medical Center, Boston, Massachusetts
Principles of Medical Consultation

A. Gordon Smith, MD
Professor and Chair of Neurology, Virginia Commonwealth University School of Medicine, Richmond, Virginia
Peripheral Neuropathies

Stephen R. Smith, MD, MHS
Professor of Medicine, Duke University School of Medicine, Durham, North Carolina
Vascular Disorders of the Kidney

Frederick S. Southwick, MD
Professor of Medicine, University of Florida College of Medicine, Gainesville, Florida
Nocardiosis

Allen M. Spiegel, MD
Dean Emeritus and Professor of Medicine, Albert Einstein College of Medicine, Bronx, New York
Principles of Endocrinology; Polyglandular Disorders

Robert Spiera, MD
Professor of Clinical Medicine, Weill Medical College of Cornell University; Director of the Scleroderma, Vasculitis, and Myositis Center, Hospital for Special Surgery, New York, New York
Giant Cell Arteritis and Polymyalgia Rheumatica

Stanley M. Spinola, MD
Professor of Microbiology and Immunology, Medicine, and Pathology and Laboratory Medicine, Indiana University School of Medicine, Indianapolis, Indiana
Chancroid

Catherine Y. Spong, MD
Professor and Chair, Department of Obstetrics and Gynecology, Paul C. MacDonald Distinguished Chair in Obstetrics and Gynecology, University of Texas Southwestern Medical School, Dallas, Texas
Medical Issues in Pregnancy

Sally P. Stabler, MD
Professor of Medicine and Cleo Scott & Mitchell Vincent Allen Chair in Hematology Research, University of Colorado School of Medicine, Aurora, Colorado
Megaloblastic Anemias

Paul Stark, MD
Professor Emeritus of Radiology, University of California, San Diego School of Medicine; Chief, Cardiothoracic Radiology, VA San Diego Healthcare System, La Jolla, California
Imaging in Pulmonary Disease

E. William St. Clair, MD
W. Lester Brooks, Jr. Professor of Medicine, Duke University School of Medicine, Durham, North Carolina
Sjögren Syndrome

Theodore S. Steiner, MD
Professor and Head, Division of Infectious Diseases, University of British Columbia, Vancouver, British Columbia, Canada
Escherichia coli *Enteric Infections*

David S. Stephens, MD
Stephen W. Schwarzmann Distinguished Professor of Medicine and Chair, Department of Medicine, Emory University School of Medicine, Atlanta, Georgia
Neisseria meningitidis *Infections*

David A. Stevens, MD
Professor of Medicine, Stanford University Medical School, Stanford, California; President, California Institute for Medical Research, Principal Investigator, Infectious Diseases Research Laboratory, California Institute for Medical Research, San Jose, California
Systemic Antifungal Agents

Dennis L. Stevens, MD, PhD
Professor of Medicine, University of Washington School of Medicine, Seattle, Washington
Nonpneumococcal Streptococcal Infections and Rheumatic Fever

M. Barry Stokes, MB BCh
Professor of Pathology and Cell Biology, Columbia University Vagelos College of Physicians and Surgeons, New York, New York
Glomerular Disorders and Nephrotic Syndromes

James K. Stoller, MD, MS
Jean Wall Bennett Professor of Medicine, Samson Global Leadership Endowed Chair, and Chairman, Education Institute, Cleveland Clinic Lerner College of Medicine, Cleveland Clinic, Cleveland, Ohio
Respiratory Monitoring in Critical Care

John H. Stone, MD, MPH
Professor of Medicine, Harvard Medical School; Edward A. Fox Chair in Medicine, Massachusetts General Hospital, Boston, Massachusetts
The Systemic Vasculitides

Richard M. Stone, MD
Professor of Medicine, Harvard Medical School; Lunder Family Chair in Leukemia, Chief of the Medical Staff, Dana-Farber Cancer Institute, Boston, Massachusetts
Myelodysplastic Syndromes

Edwin P. Su, MD
Professor of Clinical Orthopaedics, Weill Medical College of Cornell University; Attending Orthopaedic Surgeon, Hospital for Special Surgery, New York, New York
Surgical Treatment of Joint Diseases

Ronald S. Swerdloff, MD
Professor of Medicine, David Geffen School of Medicine at UCLA, Los Angeles, California; Chief, Division of Endocrinology, Metabolism and Nutrition, Harbor-UCLA Medical Center; Senior Investigator, The Lundquist Institute, Torrance, California
The Testis and Male Hypogonadism, Infertility, and Sexual Dysfunction

Heidi Swygard, MD, MPH
Professor of Medicine, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina
Approach to the Patient with a Sexually Transmitted Infection

Megan Sykes, MD
Michael J. Friedlander Professor of Medicine and Director, Columbia Center for Translational Immunology, Columbia University Vagelos College of Physicians and Surgeons, New York, New York
Transplantation Immunology

H. Keipp Talbot, MD, MPH
Associate Professor of Medicine and Health Policy, Vanderbilt University Medical Center, Nashville, Tennessee
Respiratory Syncytial Virus and Human Metapneumovirus

Rulla M. Tamimi, ScD
Professor of Population Health Sciences, Weill Medical College of Cornell University, New York, New York
Epidemiology of Cancer

Marian Tanofsky-Kraff, PhD
Professor of Medical and Clinical Psychology and of Medicine, Uniformed Services University of the Health Sciences, Bethesda, Maryland
Eating Disorders

Susan M. Tarlo, MBBS
Professor of Medicine, University of Toronto; Respiratory Physician, University Health Network, Toronto, Ontario, Canada
Occupational Lung Disease

Stephanie N. Taylor, MD
Professor of Medicine, Louisiana State University Health Sciences Center, New Orleans, Louisiana
Neisseria gonorrhoeae *Infections*

Paul S. Teirstein, MD
Chief of Cardiology and Director, Interventional Cardiology, Scripps Clinic, La Jolla, California
Interventional Diagnosis and Treatment of Coronary Artery Disease

Sam R. Telford, III, ScD
Professor of Infectious Disease and Global Health, Tufts University School of Veterinary Medicine, North Grafton, Massachusetts
Babesiosis and Other Protozoan Diseases

Rajesh V. Thakker, MD
May Professor of Medicine, Radcliffe Department of Medicine, University of Oxford, Oxford, United Kingdom
The Parathyroid Glands, Hypercalcemia, and Hypocalcemia

Judith Therrien, MD
Professor of Medicine, McGill University and Jewish General Hospital, Montreal, Quebec, Canada
Congenital Heart Disease in Adults

George R. Thompson, III, MD
Professor of Medicine, University of California–Davis School of Medicine, Sacramento, California
Endemic Mycoses

Laura Tormoehlen, MD
Associate Professor of Clinical Neurology and Emergency Medicine, Department of Neurology and Emergency Medicine, Indiana University, Indianapolis, Indiana
Chronic Poisoning: Trace Metals and Others

Antonella Tosti, MD
Fredric Brandt Endowed Professor of Dermatology, Dr. Phillip Frost Department of Dermatology and Cutaneous Surgery, University of Miami Miller School of Medicine, Miami, Florida
Diseases of Hair and Nails

Indi Trehan, MD, MPH, DTM&H
Associate Professor of Pediatrics and Adjunct Associate Professor of Global Health and of Epidemiology, University of Washington, Seattle, Washington
Severe Malnutrition

Guillermo E. Umpierrez, MD
Professor of Medicine, Emory University, Atlanta, Georgia
Diabetes Mellitus

Anthony Michael Valeri, MD
Professor of Medicine, Columbia University Vagelos College of Physicians and Surgeons; Medical Director, Hemodialysis, DaVita-Haven Dialysis Center and DaVita-Highbridge Park Dialysis Center, New York, New York
Treatment of Irreversible Renal Failure

John Varga, MD
Frederick G. Huetwell Professor and Chief, Division of Rheumatology, University of Michigan Medical School, Ann Arbor, Michigan
Systemic Sclerosis (Scleroderma)

Bradley V. Vaughn, MD
Professor of Neurology, University of North Carolina, Chapel Hill, North Carolina
Sleep Disorders

Alan P. Venook, MD
Professor of Clinical Medicine, University of California, San Francisco School of Medicine, San Francisco, California
Liver and Biliary Tract Tumors

Joseph G. Verbalis, MD
Professor of Medicine, Georgetown University; Chief, Endocrinology and Metabolism, Georgetown University Hospital, Washington, D.C.
Posterior Pituitary

Julie M. Vose, MD, MBA
Professor of Medicine and Chief, Hematology/Oncology, University of Nebraska Medical Center College of Medicine, Omaha, Nebraska
Non-Hodgkin Lymphomas

Robert M. Wachter, MD
Holly Smith Professor and Chairman, Department of Medicine, University of California, San Francisco School of Medicine, San Francisco, California
Quality, Safety, and Value

B. Timothy Walsh, MD
Ruane Professor of Psychiatry, Columbia University Vagelos College of Physicians and Surgeons and New York State Psychiatric Institute, New York, New York
Eating Disorders

Edward E. Walsh, MD
Professor of Medicine, University of Rochester School of Medicine & Dentistry, Rochester, New York
Respiratory Syncytial Virus and Human Metapneumovirus

Thomas J. Walsh, MD
Formerly Professor of Medicine, Pediatrics, and Microbiology Immunology; Director, Transplantation-Oncology Infectious Diseases, Weill Medical College of Cornell University and New York Presbyterian Hospital, New York, New York
Aspergillosis

Jeremy D. Walston, MD
Raymond and Anna Lublin Professor of Geriatric Medicine, Johns Hopkins University School of Medicine, Baltimore, Maryland
Common Clinical Sequelae of Aging

Roland B. Walter, MD, PhD, MS
Professor, Translational Science and Therapeutics Division, Fred Hutchinson Cancer Center; Professor of Medicine, University of Washington School of Medicine, Seattle, Washington
The Acute Leukemias

Christina Wang, MD
Professor of Medicine, David Geffen School of Medicine at UCLA, Los Angeles, California; Senior Associate Director, Clinical and Translational Science Institute, the Lundquist Institute and Harbor-UCLA Medical Center, Torrance, California
The Testis and Male Hypogonadism, Infertility, and Sexual Dysfunction

Kenneth K. Wang, MD
Russ and Kathy Van Cleve Professor of Gastroenterology Research, Mayo Clinic School of Medicine and Science, Rochester, Minnesota
Gastrointestinal Endoscopy

Lorraine B. Ware, MD
Professor of Medicine, Pathology, Microbiology, and Immunology, Vanderbilt University School of Medicine, Nashville, Tennessee
Acute Respiratory Failure

Cirle A. Warren, MD
Professor of Medicine, University of Virginia School of Medicine, Charlottesville, Virginia
Cryptosporidiosis

Paul B. Watkins, MD
Howard Q Ferguson Distinguished Professor, Division of Pharmacometrics and Experimental Therapeutics, Eshelman School of Pharmacy; Director, Institute for Drug Safety Sciences, University of North Carolina, Chapel Hill, North Carolina
Drug-Induced Liver Injury

Thomas J. Weber, MD
Professor of Medicine, Duke University School of Medicine, Durham, North Carolina
Approach to the Patient with Metabolic Bone Disease; Osteoporosis

Louis H. Weimer, MD
Professor of Neurology, Columbia University Vagelos College of Physicians and Surgeons, New York, New York
Nutritional and Alcohol-Related Neurologic Disorders

Geoffrey A. Weinberg, MD
Professor of Pediatrics, University of Rochester School of Medicine & Dentistry; Director, Clinical Pediatric Infectious Diseases & Pediatric HIV Program, Golisano Children's Hospital, University of Rochester Medical Center, Rochester, New York
Parainfluenza Viral Disease

Robert S. Weinstein, MD
Professor of Medicine and Director, Bone Morphometry Laboratory, University of Arkansas for Medical Sciences, Little Rock, Arkansas
Osteomalacia and Rickets

Roger D. Weiss, MD
Professor of Psychiatry, Harvard Medical School, Boston, Massachusetts; Chief, Division of Alcohol, Drugs, and Addiction, McLean Hospital, Belmont, Massachusetts
Drug Use Disorders

Roy E. Weiss, MD, PhD
Kathleen & Stanley Glaser Distinguished Chair and Chairman, Department of Medicine, University of Miami Miller School of Medicine, Miami, Florida
Neuroendocrinology and the Neuroendocrine System; Anterior Pituitary

Jeffrey I. Weitz, MD
Professor of Medicine & Biochemistry, McMaster University Michael G. DeGroote School of Medicine; Executive Director, Thrombosis & Atherosclerosis Research Institute, Hamilton, Ontario, Canada
Venous Thrombosis and Embolism

Frederick G.P. Welt, MD
Professor of Medicine, Associate Chief of Cardiovascular Medicine, and Director of the Cardiac Catheterization Laboratory, University of Utah School of Medicine, Salt Lake City, Utah
ST-Elevation Acute Myocardial Infarction and Complications of Myocardial Infarction

Richard P. Wenzel, MD, MSc
Professor and Former Chairman, Internal Medicine, Virginia Commonwealth University School of Medicine, Richmond, Virginia
Acute Bronchitis and Tracheitis

Victoria P. Werth, MD
Professor of Dermatology, University of Pennsylvania Perelman School of Medicine; Chief of Dermatology, Corporal Michael J. Crescenz VAMC, Philadelphia, Pennsylvania
Principles of Therapy of Skin Diseases

Sterling G. West, MD
Professor of Medicine, University of Colorado School of Medicine, Aurora, Colorado
Systemic Diseases in Which Arthritis Is a Feature

A. Clinton White, Jr., MD
Professor of Internal Medicine, University of Texas Medical Branch, Galveston, Texas
Cestodes

Christopher J. White, MD
Chairman and Professor of Medicine and Cardiology, Ochsner Clinical School of the University of Queensland, Ochsner Medical Institutions, New Orleans, Louisiana
Atherosclerotic Peripheral Arterial Disease

Julian White, MBBS, MD
Professor and Head, Toxinology Department, Women's and Children's Hospital, North Adelaide, South Australia, Australia
Envenomation, Bites, and Stings

Perrin C. White, MD
Audry Newman Rapoport Distinguished Chair, Pediatric Endocrinology, Professor of Pediatrics, University of Texas Southwestern Medical Center; Chief of Endocrinology, Children's Medical Center, Dallas, Texas
Sexual Development

Richard J. Whitley, MD
Distinguished Professor of Pediatrics, Loeb Eminent Scholar Chair in Pediatrics, and Professor of Microbiology, Medicine, and Neurosurgery, Pediatrics, University of Alabama at Birmingham Heersink School of Medicine, Birmingham, Alabama
Herpes Simplex Virus Infections

Michael P. Whyte, MD
Emeritus Professor of Medicine, Washington University School of Medicine in St. Louis, St. Louis, Missouri
Osteonecrosis, Osteosclerosis/Hyperostosis, and Other Disorders of Bone

Samuel Wiebe, MD, MSc
Professor of Clinical Neurosciences, Community Health Sciences, and Pediatrics; Director, Adult Epilepsy Program and Epilepsy Co-Lead, Hotchkiss Brain Institute, University of Calgary Cumming School of Medicine, Calgary, Alberta, Canada
The Epilepsies

Jeanine P. Wiener-Kronish, MD
Distinguished Henry Isaiah Dorr Professor of Research and Teaching in Anaesthesia, Harvard Medical School and Massachusetts General Hospital, Boston, Massachusetts
Overview of Anesthesia

David J. Wilber, MD
George M Eisenberg Professor of Medicine, Loyola University Chicago Stritch School of Medicine, Maywood, Illinois
Electrophysiologic Procedures and Surgery

Mark H. Wilcox, MD
Professor and Head of Medical Microbiology Research & Development, Microbiology, Leeds Teaching Hospitals & University of Leeds, Leeds, United Kingdom
Clostridial and Clostridioides *Infections*

Beverly Winikoff, MD, MPH
President, Gynuity Health Projects; Professor of Clinical Population and Family Health, Population and Family Health, Columbia University Mailman School of Public Health, New York, New York
Contraception

Jane N. Winter, MD
Professor of Medicine, Northwestern University Feinberg School of Medicine, Chicago, Illinois
Approach to the Patient with Lymphadenopathy or Splenomegaly

Marsha N. Wittink, MD, MBE
Associate Professor of Psychiatry and Family Medicine and Academic Chief, Division of Medicine in Psychiatry, University of Rochester School of Medicine & Dentistry, Rochester, New York
Medical Care of Patients with Psychiatric Diseases

Tracy A. Wolff, MD, MPH
Scientific Director, US Preventive Services Task Force Program, Center for Evidence and Practice Improvement, Agency for Healthcare Research and Quality, Rockville, Maryland
The Preventive Health Visit

Edward M. Wolin, MD
Professor of Medicine, Albert Einstein College of Medicine; Director, Neuroendocrine Tumor Program, Department of Medical Oncology, Montefiore Einstein Center for Cancer Care, Bronx, New York
Neuroendocrine Neoplasms

Gary P. Wormser, MD
Professor of Medicine and of Pathology, Microbiology and Immunology, and Pharmacology; Chief, Division of Infectious Diseases, New York Medical College, Valhalla, New York
Lyme Disease

Clyde W. Yancy, MD, MSc
Professor of Medicine, Chief of Cardiology, Professor of Medical Social Sciences, and Vice-Dean, Diversity & Inclusion, Northwestern University Feinberg School of Medicine; Associate Director, Bluhm Cardiovascular Institute, Northwestern Medicine, Chicago, Illinois
Cardiogenic Shock

Neal S. Young, MD
Chief, Hematology Branch, National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, Maryland
Parvovirus

Vincent B. Young, MD, PhD
William Henry Fitzbutler Professor of Internal Medicine/Infectious Diseases, Professor of Microbiology and Immunology, University of Michigan Medical School, Ann Arbor, Michigan
The Human Microbiome

William F. Young, Jr., MD, MSc
Tyson Family Endocrinology Clinical Professor of Medicine, Mayo Clinic College of Medicine and Science, Rochester, Minnesota
Adrenal Medulla, Catecholamines, and Pheochromocytoma

Alan S.L. Yu, MB BChir
Harry Statland and Solon Summerfield Professor, University of Kansas Medical Center; Director, The Kidney Institute, University of Kansas Medical Center, Kansas City, Kansas
Disorders of Magnesium and Phosphorus

Peter Zimetbaum, MD
Richard and Susan Smith Professor of Cardiovascular Medicine, Harvard Medical School; Associate Chief and Director of Clinical Cardiology, Beth Israel Deaconess Medical Center, Boston, Massachusetts
Bradycardias and Conduction System Delays; Supraventricular Ectopy and Tachyarrhythmias

Jane R. Zucker, MD, MSc
Assistant Commissioner, Bureau of Immunization, New York City Department of Health and Mental Hygiene, Queens, New York
Mumps

CONTENTS

VOLUME 1

SECTION I: SOCIAL AND ETHICAL ISSUES IN MEDICINE

1 Approach to Medicine, the Patient, and the Medical Profession: Medicine as a Learned and Humane Profession 2
LEE GOLDMAN, KATHLEEN A. COONEY, KIRSTEN BIBBINS-DOMINGO, MARY K. CROW, NANCY E. DAVIDSON, JEFFREY M. DRAZEN, VICTORIA J. FRASER, ALI G. GHARAVI, ANTHONY N. HOLLENBERG, S. CLAIBORNE JOHNSTON, AND ANIL K. RUSTGI

2 Bioethics in the Practice of Medicine 5
EZEKIEL J. EMANUEL

3 Palliative Care 11
ROBERT M. ARNOLD AND JEAN S. KUTNER

4 Disparities in Health and Health Care 17
JOHN Z. AYANIAN

5 Global Health 21
ALI H. MOKDAD

SECTION II: PRINCIPLES OF EVALUATION AND MANAGEMENT

6 History and Physical Examination 28
DAVID L. SIMEL

7 Approach to the Patient with Abnormal Vital Signs 32
DAVID L. SCHRIGER

8 Statistical Interpretation of Data for Clinical Decision Making 35
THOMAS H. PAYNE

9 Measuring Health and Health Care 40
CAROLYN M. CLANCY AND ERNEST MOY

10 Quality, Safety, and Value 43
ROBERT M. WACHTER AND KAVEH G. SHOJANIA

11 Population Health 47
KIRSTEN BIBBINS-DOMINGO

SECTION III: PREVENTIVE AND ENVIRONMENTAL ISSUES

12 The Preventive Health Visit 52
MARY B. BARTON AND TRACY A. WOLFF

13 Diet and Nutrition 57
DONALD D. HENSRUD

14 Physical Activity 61
WILLIAM E. KRAUS

15 Immunization 64
ANDREW T. KROGER AND WALTER A. ORENSTEIN

16 Principles of Occupational and Environmental Medicine 84
JUDITH GREEN-MCKENZIE

17 Effects of Climate Change on Health 89
JEREMY HESS AND KRISTIE EBI

18 Radiation Injury 91
DAVID J. BRENNER

19 Bioterrorism 95
MARK G. KORTEPETER AND THEODORE J. CIESLAK

20 Chronic Poisoning: Trace Metals and Others 101
LOUISE W. KAO, LAURA TORMOEHLEN, AND BLAKE A. FROBERG

SECTION IV: AGE-SPECIFIC AND GERIATRIC MEDICINE

21 Adolescent Medicine 110
DEBRA K. KATZMAN AND S. TODD CALLAHAN

22 Epidemiology of Aging 114
LOUISE ARONSON

23 Geriatric Assessment 116
C. SETH LANDEFELD

24 Common Clinical Sequelae of Aging 120
JEREMY D. WALSTON

SECTION V: CLINICAL PHARMACOLOGY

25 Principles of Drug Therapy 126
ROBERT B. DIASIO

26 Pain 133
STEVEN P. COHEN

27 Biology of Addiction 142
ERIC J. NESTLER

28 Immunomodulatory Drugs 144
ANNE R. BASS AND INEZ ROGATSKY

29 Biologic Agents and Signaling Inhibitors 149
NANCY J. OLSEN AND JOHN J. O'SHEA

30 Complementary and Integrative Medicine 153
FREDERICK M. HECHT

SECTION VI: GENETICS

31 Principles of Genetics 158
BRUCE R. KORF AND NITA A. LIMDI

32 Clinical Genomics—Genome Structure and Variation 160
LESLIE G. BIESECKER

33 Applications of Molecular Technologies to Clinical Medicine 165
GEOFFREY S. GINSBURG

34 Regenerative Medicine, Cell Therapy, and Gene Therapy 169
LIOR GEPSTEIN AND KARL SKORECKI

SECTION VII: PRINCIPLES OF IMMUNOLOGY AND INFLAMMATION

35 The Innate and Adaptive Immune Systems 182
MARY K. CROW

36 Tissue Injury and Repair 191
JANE E. SALMON

37 Complement System in Disease 196
JOHN P. ATKINSON AND V. MICHAEL HOLERS

38 Transplantation Immunology 203
MEGAN SYKES

SECTION VIII: HEART DISEASES

39 Approach to the Patient with Possible Cardiovascular Disease 210
LEE GOLDMAN

40 Epidemiology of Cardiovascular Disease 219
DONALD M. LLOYD-JONES

41 Cardiac and Circulatory Function 223
ANDREW R. MARKS

Copyrighted material

42 Electrocardiography 228
LEONARD GANZ AND MARK S. LINK

43 Echocardiography 235
CATHERINE M. OTTO

44 Noninvasive Cardiac Imaging 244
CHRISTOPHER M. KRAMER, VASKEN DILSIZIAN, AND KLAUS D. HAGSPIEL

45 Heart Failure: Epidemiology, Pathobiology, and Diagnosis 254
JOSEPH G. ROGERS AND CHRISTOPHER M. O'CONNOR

46 Heart Failure: Treatment and Prognosis 262
JOHN J.V. MCMURRAY AND MARC A. PFEFFER

47 Diseases of the Myocardium and Endocardium 279
PERRY M. ELLIOTT AND IACOPO OLIVOTTO

48 Principles of Electrophysiology 298
GLENN I. FISHMAN

49 Approach to the Patient with Suspected Arrhythmia 303
JEFFREY E. OLGIN

50 Cardiac Arrest and Life-Threatening Arrhythmias 312
ROBERT J. MYERBURG AND RACHEL LAMPERT

51 Bradycardias and Conduction System Delays 317
PETER ZIMETBAUM AND LEE GOLDMAN

52 Supraventricular Ectopy and Tachyarrhythmias 322
PETER ZIMETBAUM AND LEE GOLDMAN

53 Ventricular Arrhythmias 332
HASAN GARAN

54 Electrophysiologic Procedures and Surgery 340
PETER A. SANTUCCI AND DAVID J. WILBER

55 Congenital Heart Disease in Adults 347
JUDITH THERRIEN AND ARIANE J. MARELLI

56 Angina Pectoris and Chronic Ischemic Heart Disease 356
WILLIAM E. BODEN

57 Acute Coronary Syndrome: Unstable Angina and Non–ST Elevation Myocardial Infarction 370
RICHARD A. LANGE AND DEBABRATA MUKHERJEE

58 ST-Elevation Acute Myocardial Infarction and Complications of Myocardial Infarction 380
FREDERICK G.P. WELT AND JAMES C. FANG

59 Interventional Diagnosis and Treatment of Coronary Artery Disease 393
PAUL S. TEIRSTEIN AND AJAY J. KIRTANE

60 Valvular Heart Disease 400
BLASE A. CARABELLO AND SUSHEEL KODALI

61 Infective Endocarditis 413
VANCE G. FOWLER, JR., ARNOLD S. BAYER, AND LARRY M. BADDOUR

62 Pericardial Diseases 423
BRIAN D. HOIT AND JAE K. OH

SECTION IX: VASCULAR MEDICINE

63 Diseases of the Aorta 436
JOSHUA A. BECKMAN

64 Arterial Hypertension 444
JOHN M. FLACK

65 Atherosclerotic Peripheral Arterial Disease 461
CHRISTOPHER J. WHITE

66 Other Peripheral Arterial Diseases 467
JOHN R. BARTHOLOMEW

67 Thrombotic Disorders: Hypercoagulable States 475
ANDREW I. SCHAFER

68 Venous Thrombosis and Embolism 482
JEFFREY I. WEITZ AND JOHN W. EIKELBOOM

69 Pulmonary Hypertension 493
MARIUS M. HOEPER AND VALLERIE MCLAUGHLIN

70 Antithrombotic and Antiplatelet Therapy 501
RICHARD C. BECKER AND THOMAS L. ORTEL

SECTION X: RESPIRATORY DISEASES

71 Approach to the Patient with Respiratory Disease 512
MONICA KRAFT

72 Imaging in Pulmonary Disease 519
PAUL STARK

73 Respiratory Testing and Function 528
PAUL D. SCANLON AND ALEXANDER S. NIVEN

74 Disorders of Ventilatory Control 534
ATUL MALHOTRA AND FRANK POWELL

75 Asthma 537
JEFFREY M. DRAZEN AND ELISABETH H. BEL

76 Chronic Obstructive Pulmonary Disease 547
JOHN REILLY

77 Cystic Fibrosis 556
HARTMUT GRASEMANN

78 Bronchiectasis, Atelectasis, and Cavitary or Cystic Lung Diseases 560
ANNE E. O'DONNELL

79 Alveolar Filling Disorders 566
STEPHANIE M. LEVINE

80 Interstitial Lung Disease 570
GANESH RAGHU AND FERNANDO J. MARTINEZ

81 Occupational Lung Disease 584
SUSAN M. TARLO AND CARRIE A. REDLICH

82 Physical and Chemical Injuries of the Lung 591
DAVID C. CHRISTIANI AND LISA A. MAIER

83 Sarcoidosis 599
MICHAEL C. IANNUZZI

84 Acute Bronchitis and Tracheitis 605
GONZALO M. BEARMAN AND RICHARD P. WENZEL

85 Overview of Pneumonia 606
LINDSEY R. BADEN, MARIE R. GRIFFIN, AND MICHAEL KLOMPAS

86 Diseases of the Diaphragm, Chest Wall, Pleura, and Mediastinum 619
F. DENNIS MCCOOL

87 Interventional and Surgical Approaches to Lung Disease 630
DAVID J. FELLER-KOPMAN AND MALCOLM M. DECAMP

SECTION XI: CRITICAL CARE MEDICINE

88 Approach to the Patient in a Critical Care Setting 636
DEBORAH J. COOK

89 Respiratory Monitoring in Critical Care 639
JAMES K. STOLLER AND NICHOLAS S. HILL

90 Acute Respiratory Failure 642
MICHAEL A. MATTHAY AND LORRAINE B. WARE

91 Mechanical Ventilation 652
LAURENT BROCHARD AND ARTHUR S. SLUTSKY

92 Approach to the Patient with Shock 658
DEREK C. ANGUS

93 Cardiogenic Shock 665
STEVEN M. HOLLENBERG AND CLYDE W. YANCY

94 Shock Syndromes Related to Sepsis 669
ANTHONY C. GORDON AND JAMES A. RUSSELL

95 Disorders Due to Heat and Cold 678
MICHAEL N. SAWKA AND FRANCIS G. O'CONNOR

96 Acute Poisoning 682
LEWIS S. NELSON AND DIANE P. CALELLO

97 Medical Aspects of Trauma and Burns 698
ROBERT L. SHERIDAN

98 Envenomation, Bites, and Stings 704
STEVEN A. SEIFERT, RICHARD C. DART, AND JULIAN WHITE

99 Rhabdomyolysis 714
FRANCIS G. O'CONNOR AND PATRICIA A. DEUSTER

Copyrighted material

SECTION XII: RENAL AND GENITOURINARY DISEASES

100 Approach to the Patient with Renal Disease 720
ALI G. GHARAVI AND DONALD W. LANDRY

101 Structure and Function of the Kidneys 729
QAIS AL-AWQATI AND JONATHAN BARASCH

102 Disorders of Sodium and Water 733
QAIS AL-AWQATI AND JAI RADHAKRISHNAN

103 Potassium Disorders 745
JULIAN LAWRENCE SEIFTER

104 Acid-Base Disorders 752
JULIAN LAWRENCE SEIFTER

105 Disorders of Magnesium and Phosphorus 766
ALAN S.L. YU

106 Acute Kidney Injury 770
ANUPAM AGARWAL AND JONATHAN BARASCH

107 Glomerular Disorders and Nephrotic Syndromes 776
JAI RADHAKRISHNAN AND M. BARRY STOKES

108 Interstitial Nephritis 790
CYBELE GHOSSEIN AND ERIC G. NEILSON

109 Diabetes and the Kidney 795
RAYMOND C. HARRIS

110 Vascular Disorders of the Kidney 799
THOMAS M. COFFMAN AND STEPHEN R. SMITH

111 Nephrolithiasis 803
DAVID A. BUSHINSKY

112 Cystic Kidney Diseases 808
M. AMIN ARNAOUT

113 Hereditary Nephropathies and Developmental Renal/Urinary Abnormalities 815
LISA M. GUAY-WOODFORD

114 Benign Prostatic Hyperplasia and Prostatitis 821
STEVEN A. KAPLAN

115 Urinary Incontinence 827
NEIL M. RESNICK AND CATHERINE E. DUBEAU

116 Chronic Kidney Disease 831
ANDREW S. LEVEY AND MARK J. SARNAK

117 Treatment of Irreversible Renal Failure 840
DAVID COHEN AND ANTHONY MICHAEL VALERI

SECTION XIII: GASTROINTESTINAL DISEASES

118 Approach to the Patient with Gastrointestinal Disease 850
KENNETH R. MCQUAID

119 Diagnostic Imaging Procedures in Gastroenterology 866
LAURA R. CARUCCI

120 Gastrointestinal Endoscopy 875
KENNETH K. WANG

121 Gastrointestinal Hemorrhage 882
THOMAS O. KOVACS AND DENNIS M. JENSEN

122 Disorders of Gastrointestinal Motility 887
MICHAEL CAMILLERI

123 Irritable Bowel and Functional Upper Gastrointestinal Syndromes 892
LIN CHANG

124 Diseases of the Esophagus 901
GARY W. FALK AND DAVID A. KATZKA

125 Acid Peptic Disease 913
ERNST J. KUIPERS

126 Approach to the Patient with Diarrhea and Malabsorption 923
CAROL E. SEMRAD

127 Inflammatory Bowel Disease 941
GARY R. LICHTENSTEIN

128 Inflammatory and Anatomic Diseases of the Intestine, Peritoneum, Mesentery, and Omentum 951
JOHN F. KUEMMERLE

129 Vascular Diseases of the Gastrointestinal Tract 959
CHARLES J. KAHI

130 Pancreatitis 969
CHRIS E. FORSMARK

131 Diseases of the Rectum and Anus 977
ROBERT D. MADOFF AND GENEVIEVE B. MELTON

SECTION XIV: DISEASES OF THE LIVER AND BILIARY SYSTEM

132 Approach to the Patient with Liver Disease 986
PAUL MARTIN

133 Approach to the Patient with Jaundice or Abnormal Liver Tests 993
KEVIN M. KORENBLAT

134 Acute Viral Hepatitis 1002
JEAN-MICHEL PAWLOTSKY

135 Chronic Viral and Autoimmune Hepatitis 1009
JEAN-MICHEL PAWLOTSKY

136 Drug-Induced Liver Injury 1017
PAUL B. WATKINS

137 Bacterial, Parasitic, Fungal, and Granulomatous Liver Diseases 1022
K. RAJENDER REDDY

138 Alcoholic and Nonalcoholic Steatohepatitis 1031
NAGA P. CHALASANI AND JACQUELYN MAHER

139 Cirrhosis and Its Sequelae 1035
GUADALUPE GARCIA-TSAO

140 Liver Failure and Transplantation 1043
ROBERT J. FONTANA

141 Diseases of the Gallbladder and Bile Ducts 1049
EVAN L. FOGEL AND STUART SHERMAN

SECTION XV: HEMATOLOGIC DISEASES

142 Hematopoiesis and Hematopoietic Growth Factors 1064
KENNETH KAUSHANSKY

143 The Peripheral Blood Smear 1066
BARBARA J. BAIN

144 Approach to the Anemias 1074
ROBERT T. MEANS, JR.

145 Microcytic and Hypochromic Anemias 1082
THOMAS G. DELOUGHERY

146 Autoimmune and Intravascular Hemolytic Anemias 1086
MARC MICHEL

147 Hemolytic Anemias: Red Blood Cell Membrane and Metabolic Defects 1093
PATRICK G. GALLAGHER

148 The Thalassemias 1102
MARIA DOMENICA CAPPELLINI

149 Sickle Cell Disease and Other Hemoglobinopathies 1109
JO HOWARD

150 Megaloblastic Anemias 1117
SALLY P. STABLER

151 Aplastic Anemia and Related Bone Marrow Failure States 1125
AMY E. DEZERN AND ROBERT A. BRODSKY

152 Polycythemia Vera, Essential Thrombocythemia, and Primary Myelofibrosis 1130
JASON GOTLIB

153 Leukocytosis and Leukopenia 1140
NANCY BERLINER

154 Approach to the Patient with Lymphadenopathy or Splenomegaly 1148
JANE N. WINTER

155 Histiocytoses 1154
BARRETT J. ROLLINS AND NANCY BERLINER

156 Eosinophilic Syndromes 1162
AMY D. KLION

Copyrighted material

157 Approach to the Patient with Bleeding or Thrombosis 1165
ANDREW I. SCHAFER

158 Thrombocytopenia 1170
CHARLES S. ABRAMS

159 Von Willebrand Disease and Hemorrhagic Abnormalities of Platelet and Vascular Function 1180
JORGE DI PAOLA AND JAMES S. O'DONNELL

160 Coagulation Factor Deficiencies 1187
MARGARET V. RAGNI

161 Disseminated Intravascular Coagulation and Bleeding in Liver Failure 1195
ANDREW I. SCHAFER

162 Transfusion Medicine 1199
BETH H. SHAZ AND CHRISTOPHER D. HILLYER

163 Hematopoietic Cell Transplantation 1206
NELSON J. CHAO AND ARMAND KEATING

SECTION XVI: ONCOLOGY

164 Approach to the Patient with Cancer 1214
JAMES H. DOROSHOW

165 Epidemiology of Cancer 1243
RULLA M. TAMIMI

166 Cancer Biology and Genetics 1247
BEN HO PARK

167 Myelodysplastic Syndromes 1252
RICHARD M. STONE

168 The Acute Leukemias 1259

ROBIN K. KELLEY AND ALAN P. VENOOK

182 Tumors of the Kidney, Bladder, Ureters, and Renal Pelvis 1362
DEAN F. BAJORIN

183 Breast Cancer and Benign Breast Disorders 1368
NANCY E. DAVIDSON

184 Gynecologic Cancers 1375
DEBORAH K. ARMSTRONG

185 Testicular Cancer 1382
LAWRENCE H. EINHORN

186 Prostate Cancer 1384
KATHLEEN A. COONEY AND ELISABETH I. HEATH

187 Malignant Bone Tumors, Sarcomas, and Other Soft Tissue Neoplasms 1387
ROBIN L. JONES

188 Melanoma and Nonmelanoma Skin Cancers 1390
LYNN M. SCHUCHTER

VOLUME 2

SECTION XVII: METABOLIC DISEASES

189 Approach to Inborn Errors of Metabolism 1398
WILLIAM J. CRAIGEN

190 Disorders of Lipid Metabolism 1404
JENNIFER G. ROBINSON

191 Glycogen Storage Diseases 1415
PRIYA S. KISHNANI

192 Lysosomal Storage Diseases 1418
DONNA M. KRASNEWICH AND ELLEN SIDRANSKY

193 Homocystinuria and Hyperhomocysteinemia 1425
MANUEL SCHIFF AND HENK J. BLOM

194 The Porphyrias 1428
RICHARD J. HIFT

195 Wilson Disease 1436
MICHAEL L. SCHILSKY

196 Iron Overload (Hemochromatosis) 1438
KRIS V. KOWDLEY

SECTION XVIII: NUTRITIONAL DISEASES

197 Severe Malnutrition 1444
MARK J. MANARY AND INDI TREHAN

198 Malnutrition: Assessment and Support 1446
TOMMY E. CEDERHOLM AND INGVAR G. BOSAEUS

199 Vitamins, Trace Minerals, and Other Micronutrients 1451
JOEL B. MASON AND SARAH L. BOOTH

200 Eating Disorders 1461
EVELYN ATTIA, MARIAN TANOFSKY-KRAFF, AND B. TIMOTHY WALSH

201 Obesity 1463
MICHAEL D. JENSEN AND DANIEL H. BESSESEN

SECTION XIX: ENDOCRINE DISEASES

202 Approach to the Patient with Endocrine Disease 1472
DAVID R. CLEMMONS AND LYNNETTE K. NIEMAN

203 Principles of Endocrinology 1473
ALLEN M. SPIEGEL

204 Neuroendocrinology and the Neuroendocrine System 1476
ROY E. WEISS

205 Anterior Pituitary 1482
ROY E. WEISS

206 Posterior Pituitary 1498
JOSEPH G. VERBALIS

207 Thyroid 1504
ELIZABETH N. PEARCE AND ANTHONY N. HOLLENBERG

208 Adrenal Cortex 1520
LYNNETTE K. NIEMAN

209 Adrenal Medulla, Catecholamines, and Pheochromocytoma 1529
WILLIAM F. YOUNG, JR.

210 Diabetes Mellitus 1534
KETAN K. DHATARIYA, GUILLERMO E. UMPIERREZ, AND JILL P. CRANDALL

211 Hypoglycemia 1551
KHALID HUSSAIN

212 Polyglandular Disorders 1558
LYNNETTE K. NIEMAN AND ALLEN M. SPIEGEL

213 Neuroendocrine Neoplasms 1561
EDWARD M. WOLIN AND ROBERT T. JENSEN

APPROACH TO MEDICINE, THE PATIENT, AND THE MEDICAL PROFESSION: MEDICINE AS A LEARNED AND HUMANE PROFESSION

LEE GOLDMAN, KATHLEEN A. COONEY, KIRSTEN BIBBINS-DOMINGO, MARY K. CROW, NANCY E. DAVIDSON, JEFFREY M. DRAZEN, VICTORIA J. FRASER, ALI G. GHARAVI, ANTHONY N. HOLLENBERG, S. CLAIBORNE JOHNSTON, AND ANIL K. RUSTGI

APPROACH TO MEDICINE

THE HISTORIC EVOLUTION

Medicine is a profession that incorporates science and the scientific method with the art of being a physician. The art of tending to the sick is as old as humanity itself. Even in modern times, the art of caring and comforting, guided by common sense over millennia as well as by a more recent, systematic approach to medical ethics (Chapter 2), remains the cornerstone of medicine. Without these humanistic qualities, the application of the modern science of medicine is suboptimal, ineffective, or even detrimental.

However, the essential humanistic qualities of caring and comforting can achieve full benefit only if they are coupled with an understanding of how medical science can and should be applied to all individuals regardless of their race, sex, sexual orientation, or other characteristics. Without this knowledge, comforting may be inappropriate or misleading and caring may be ineffective or counterproductive if it inhibits a sick person from obtaining appropriate, scientific medical care.

The concept of *internal medicine*, which began in 19th-century Germany, was to emphasize the underlying pathobiologic causes of disease, not just the patterns or progression of clinical manifestations. Modern medicine is based on increasingly accelerated discoveries made with this approach over the past 150 years, during which time human life expectancy has approximately doubled.[1] *Goldman-Cecil Medicine* incorporates this tradition by showing how pathobiologic abnormalities cause clinical manifestations and by emphasizing how therapies can modify this underlying pathophysiology and improve the patient's well-being.

CONTEMPORARY MEDICAL SCIENCE

The contemporary practice of medicine now includes an increasingly detailed understanding of cellular, subcellular, molecular, genetic, and epigenetic mechanisms of health and disease. For example, the understanding of microbial pathogenesis as well as that of many noninfectious (as we understand them now) inflammatory diseases (Chapter 236) is now guided by a detailed understanding of the human immune system and its response to foreign antigens (Chapters 35 to 37).

Health, disease, and an individual's interaction with the environment are also substantially determined by genetics and epigenetics. In addition to monogenic conditions, medical science increasingly understands the complex interactions that underlie multigenic traits, including diabetes mellitus, cancer, and other common health conditions (Chapter 32). The decoding of the human genome holds the promise that personalized health care increasingly can be targeted according to an individual's genetic profile, in terms of screening and presymptomatic disease management, as well as in terms of specific medications, their complex interactions, and their adjusted dosing schedules.[2]

Knowledge of the structure and physical forms of proteins helps explain abnormalities as diverse as sickle cell anemia (Chapter 149) and prion-related diseases (Chapter 371). Proteomics, which is the large-scale analysis of proteins produced by an organism, also holds extraordinary promise for developing drug targets for more specific and effective therapies. Increasingly, the effects of nurture and the environment, expressed as epigenetic modifications of DNA or chromatin, are also being deciphered, with the potential for future therapeutic interventions. A striking illustration is evolving evidence that the gut microbiome is shaped at the time of birth during vaginal delivery. Advances in our understanding of the human microbiome also raise the possibility that our complex interactions with microbes, which outnumber the cells in the human body by a factor of 10, will help explain conditions ranging from inflammatory bowel disease (Chapter 127) to obesity (Chapter 201).

EVIDENCE-BASED MEDICINE

Concurrent with these advances in fundamental human biology has been a dramatic shift in methods for evaluating the application of scientific advances to the individual patient and to populations. The randomized controlled trial, sometimes with thousands of patients at multiple institutions, has replaced anecdote as the most robust method for measuring the benefits and optimal uses of diagnostic and therapeutic interventions (Chapter 8). Yet this approach to the evaluation of therapeutics and diagnostics is being challenged. To reduce costs as well as overcome inefficiencies, redundancies, and the late failure of many clinical trials (at the phase III stage) inherent in classic randomized controlled trials, technologic advances are enabling new methods, tools, and approaches to bring clinical trials into the 21st century. These methods include disease modeling and simulation, alternative trial methods such as response-adaptive randomized designs (Chapter 8), real-world pragmatic trials, population-based studies, use of artificial intelligence and data science, implementation science, community-engaged research, novel objective outcome measures, and engagement of clinical trial "participants" (rather than "human subjects") to expand the pool of individuals willing to be involved in clinical research.

As research progresses from studies that show biologic effect, to studies that elucidate dosing schedules and toxicity, and finally to controlled trials that assess true clinical benefit, the metrics of measuring outcome has also improved from subjective impressions of physicians or patients to reliable and valid measures of morbidity, quality of life, functional status, and other patient-oriented outcomes (Chapter 9). These marked improvements in the scientific methodology of clinical investigation have expedited extraordinary changes in clinical practice, such as recanalization therapy for acute myocardial infarction (Chapter 58) and aspiration therapy for cerebrovascular clots (Chapter 377), which focus on important outcomes, including not only death but also physical function and quality of life. Just as physicians in the 21st century must understand advances in fundamental biology, similar understanding of the fundamentals of clinical study design as it applies to diagnostic and therapeutic interventions is important.

An understanding of human genomics and genetics can also help stratify and refine the approach to clinical trials by helping researchers identify fewer patients with a more homogeneous disease pattern to study the efficacy of an intervention. Such an approach has been especially relevant in cancer, in which tumors with certain genetic mutations can respond to a drug specifically designed for that target, whereas other tumors with similar histologic but different molecular characteristics will not. Germline genetic testing is now common in clinical practice, and molecular biomarkers are increasingly important for screening, surveillance, early detection, risk stratification, and therapy. Systems biology, which is the integration of all these techniques, can enable the development of new predictive, preventive, and personalized approaches to disease.

CHANGES IN MEDICAL PRACTICE

This explosion in medical knowledge and clinical research has led to increasing specialization and subspecialization, defined initially by organ system and more recently by locus of principal activity (inpatient as compared with outpatient), reliance on manual skills (proceduralist vs. nonproceduralist), or participation in research. Sophisticated computerized analyses of radiographs,[3] computed tomographic scans, magnetic resonance images, retinal images,[4] and histopathologic specimens are also poised to revolutionize the interpretation of these tests, much as computerized electrocardiographic interpretation (Chapter 42) changed clinical cardiology.

Computerized health records can avoid duplication of tests, ensure that care is coordinated among the patient's various health care providers, and increase the value of health care. Real-time electronic monitoring can be used to alert physicians about patients whose vital signs (Chapter 7) might warrant urgent evaluation to avoid more serious clinical decompensation.[5] Data derived from electronic medical records can detect patterns of drug side effects or interactions that can then guide molecular analyses that confirm new risks or even genetic diseases.[6]

Although it is too soon to know whether patients would routinely benefit from sequencing and analysis of their exome or full genome, such information is increasingly becoming affordable and more accurate, with potential usefulness for identifying Mendelian disease patterns[7] and informing reproductive planning. Despite much hope, however, genetic profiling of germline sequences has had limited positive impact on drug selection and dosing.

ABSTRACT

The medical profession incorporates both the science of medicine as well as the art of being a physician. Physicians cannot help patients unless they are well-grounded in the latest information about medical diagnosis and management, which increasingly is based on randomized clinical trials as well as on patient-specific information, including genetics and genomics. However, this scientific expertise also must be applied in the context of understanding the patient as an individual person. In applying both scientific knowledge and medical professionalism, physicians must recognize the importance of the social determinants of health and be champions for diversity, equity, inclusion, and social justice as they advocate for and take care of individual patients in the context of broader societal issues.

NEW THERAPEUTICS

Gene therapy is currently approved by the U.S. Food and Drug Administration (FDA) for only a few diseases—Leber congenital amaurosis (Chapter 391), retinal dystrophy, beta thalassemia, hemophilia (Chapter 160), and spinal muscular atrophy (Chapter 387) are examples—but many more gene therapies are in development and clinical testing. Specific DNA sequences can now be targeted with clustered regularly interspaced short palindromic repeats (CRISPR)-associated nucleases to inactivate genes or to correct a pathogenic mutation back to the reference sequence. This technique has already demonstrated durable benefits for patients with hemophilia (Chapter 160).

Cell-based therapy is now beginning to provide vehicles for the delivery of cells engineered to address a patient's particular chimeric antigen receptor (CAR).[8] CAR-T cell therapy is FDA-approved for conditions such as non-Hodgkin lymphoma (Chapter 171), acute lymphoblastic leukemia (Chapter 168), multiple myeloma (Chapter 173), melanoma (Chapter 188), and prostate cancer (Chapter 186), and it is being actively tested in other conditions. Although effective in many cases, cost and severe side effects, especially the so-called cytokine release syndrome, currently limit its widespread use.

Regenerative medicine to help heal injured or diseased organs, by the administration of cells modified to meet a patient's needs, is in its infancy. However, cultured chondrocytes are now FDA-approved to repair cartilaginous defects of the femoral condyle and the knee.

Immune checkpoint inhibitors have revolutionized the approach to treating cancer, initially melanoma (Chapter 188),[9] but now also a wide range of malignancies, with future potential efficacy for the treatment of refractory infectious diseases, autoimmune diseases, and serious allergic disorders.[10] Messenger RNA (mRNA) vaccines, which deliver antigen-encoding mRNA into immune cells, where they stimulate an adaptive immune response, have revolutionized the approach to preventing severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2; Chapter 337) and are increasingly being applied to other infections.[11]

SOCIETAL IMPLICATIONS

Extraordinary advances in the science and practice of medicine have transformed the global burden of disease. For example, vaccines and other population-wide interventions, such as screening for and treating hypertension and hypercholesterolemia, have greatly reduced the burden of infectious and cardiovascular diseases. In many countries, life expectancies for men and women have been increasing, a greater proportion of deaths are occurring among people older than age 70 years, and far fewer children are dying before the age of 5 years. In the United States, however, overall life expectancy has declined in the last several years. Explanations include not only the unprecedented SARS-CoV-2 pandemic and the coronavirus-2019 (COVID-19) disease it causes, but also obesity-related diseases[12] as well as so-called deaths of despair owing to alcohol, drug overdoses, and suicide.[13] Disability from conditions such as substance abuse, mental health disorders, injuries, diabetes, musculoskeletal disease, and chronic respiratory disease have become increasingly important issues for all health systems.

Globally, but also within the United States, substantial health disparities persist based on geography, race, ethnicity, socioeconomic status, and often sexual orientation and gender identity.[14] Physicians must understand historic as well as current health disparities and the social determinants of health. They must strive to understand the benefits and needs of diverse populations and individual patients, and they must be advocates for equity, inclusion, access, and social justice in all aspects of medicine and health care.[15]

APPROACH TO THE PATIENT

Patients commonly have complaints (symptoms), but at least one third of these symptoms will not be readily explainable by any detectable abnormalities on examination (signs) or on laboratory testing. Even in the modern era of advanced diagnostic testing, the history and physical examination are estimated to contribute at least 75% of the information that informs the evaluation of symptoms, and symptoms that are not explained on initial comprehensive evaluation rarely are manifestations of a serious underlying disease. Conversely, asymptomatic patients may have signs or laboratory abnormalities, and laboratory abnormalities can occur in the absence of symptoms or signs.

Symptoms and signs commonly define *syndromes*, which may be the common final pathway of a wide range of pathophysiologic alterations. The fundamental basis of internal medicine is that diagnosis should elucidate the pathophysiologic explanation for symptoms and signs so that therapy may improve the underlying abnormality, not just attempt to suppress the abnormal symptoms or signs.

When patients seek care from physicians, they may have manifestations or exacerbations of known conditions or they may have symptoms and signs that suggest malfunction of a particular organ system. Sometimes the pattern of symptoms and signs is highly suggestive or even pathognomonic for a particular disease process. In these situations, in which the physician is focusing on a particular disease, *Goldman-Cecil Medicine* provides scholarly yet practical approaches to the epidemiology, pathobiology, clinical manifestations, diagnosis, treatment, prevention, and prognosis of entities such as acute myocardial infarction (Chapter 58), chronic obstructive lung disease (Chapter 76), inflammatory bowel disease (Chapter 127), gallstones (Chapter 141), rheumatoid arthritis (Chapter 243), hypothyroidism (Chapter 207), and tuberculosis (Chapter 299), as well as newly described disorders such as emerging zoonoses (Chapter 303), small fiber neuropathies (Chapter 388), mitochondrial diseases (Chapter 389), autoinflammatory diseases (Chapter 240), and clonal disorders of indeterminate potential (Chapter 142).

Many patients, however, have undiagnosed symptoms, signs, or laboratory abnormalities that cannot be immediately ascribed to a particular disease or cause. Whether the initial manifestation is chest pain (Chapter 39), diarrhea (Chapter 126), neck or back pain (Chapter 369), or a variety of more than 100 common symptoms, signs, or laboratory abnormalities, *Goldman-Cecil Medicine* provides tables, figures, and entire chapters to guide the approach to diagnosis and therapy (see E-Table 1-1 or the table on the inside back cover of the printed book). By virtue of this dual approach to known disease as well as to undiagnosed abnormalities, this textbook, similar to the modern practice of medicine, applies directly to patients regardless of their mode of manifestation or degree of previous evaluation.

CLINICAL REASONING AND DECISION-MAKING

The patient-physician interaction proceeds through many phases of clinical reasoning and decision making. The interaction begins with an elucidation of complaints or concerns in a respectful and socially conscious approach, followed by inquiries or evaluations to address these concerns in increasingly precise ways. The process commonly requires a careful history or physical examination (Chapter 6), ordering of diagnostic tests, integration of clinical findings with test results, understanding of the risks and benefits of the possible courses of action, and careful consultation with the patient and family to develop future plans. Physicians can increasingly call on a growing literature of evidence-based medicine to guide the process so that benefit is maximized while respecting individual variations in different patients. Throughout *Goldman-Cecil Medicine*, the best current evidence is highlighted with specific grade A references that can be accessed directly in the electronic version.

The increasing availability of evidence from randomized trials to guide the approach to diagnosis and therapy should not be equated with "cookbook" medicine. Evidence and the guidelines that are derived from it emphasize proven approaches for patients with specific characteristics. Substantial clinical judgment is required to determine whether the evidence and guidelines apply to individual patients and to recognize the occasional exceptions. Even more judgment is required in the many situations in which evidence is absent or inconclusive.[16] Evidence must be tempered by patients' preferences, although it is a physician's responsibility to avoid pre-judgment and to emphasize evidence when presenting alternative options to the patient. The adherence of a patient to a specific regimen is likely to be enhanced if the patient also understands the rationale and evidence behind the recommended option.

To optimize medical care, the physician must understand the patient as a person. This fundamental precept of doctoring includes an understanding of the patient's sexual orientation and gender identity, cultural background, social situation, family issues, financial constraints, access to health insurance, trust in the health care system, and preferences for different types of care and outcomes, ranging from maximum prolongation of life to the relief of pain and suffering (Chapters 2 and 3). If the physician does not appreciate and address these issues, the science of medicine cannot be applied appropriately, and even the most knowledgeable physician will fail to achieve the desired outcomes.

Even as physicians become increasingly aware of new discoveries, patients can obtain their own information from a variety of sources, some of which are of questionable reliability.[17] The increasing use of alternative and complementary therapies (Chapter 30) is an example of patients' frequent dissatisfaction with prescribed medical therapy. Physicians should keep an open mind regarding unproven options but must advise their patients carefully if such options may carry any degree of potential risk, including the risk that they may be relied on to substitute for proven approaches.

The principle of patient autonomy asserts that physicians make recommendations but patients make the final decisions (Chapter 2). The physician is an

expert advisor who must inform and empower the patient to make decisions by integrating scientific data with their preferences and values. The physician must have an open dialogue with the patient and family regarding the full range of options and encourage shared decision-making whenever appropriate.

The rise of telemedicine, stimulated by the social distancing in response to the COVID-19 pandemic, promises to increase accessibility but at the potential detriment of the personal closeness of the patient-doctor relationship.[18] Physicians and the medical profession have the opportunity to use this indisputably convenient tool to extend health care to underserved and vulnerable populations worldwide, but they must remain vigilant to benefit from its virtues, minimize its limitations, and not exacerbate health disparities based on access to digital technology.[19]

INCORPORATING A PUBLIC HEALTH FOCUS

The physician does not exist in a vacuum, but rather as part of a complicated and extensive system of medical care and public health. In premodern times and even today in some resource-limited countries, the most important ways to promote health and reduce disease are to ensure basic hygiene, clean water, and adequate nutrition (Chapter 11). In resource-limited and high-income countries, adoption of healthy lifestyles, including better diet (Chapter 13) and appropriate exercise (Chapter 14), are the keys to reducing the epidemics of obesity (Chapter 201), coronary disease (Chapter 40), and diabetes (Chapter 210). Public health interventions to provide immunizations (Chapter 15) and to reduce injuries and the use of tobacco (Chapter 363), illicit drugs (Chapter 365), and excess alcohol (Chapter 364) can collectively produce more health benefits than nearly any other imaginable health intervention. As emphasized by the COVID-19 pandemic (Chapters 335 to 337), the public health system must play a key role in informing the populace and in promoting guidelines for individuals as well as for the health care profession.

APPROACH TO THE MEDICAL PROFESSION

Medical professionalism should emphasize three fundamental principles: the primacy of patient welfare, patient autonomy, and social justice. As modern medicine brings a plethora of diagnostic and therapeutic options, the interactions of the physician with the patient and society become more complex and potentially fraught with ethical dilemmas (Chapter 2). To help provide a moral compass that is not only grounded in tradition but also adaptable to modern times, the primacy of patient welfare emphasizes the fundamental principle of the medical profession. The physician's altruism, which begets the patient's trust, must be impervious to the social, economic, bureaucratic, and political challenges that are faced by the physician and the patient (Chapter 4).

To promote these fundamental principles, a series of professional responsibilities (Table 1-1) represents practical, daily traits that benefit the physician's own patients and society as a whole. Physicians who use these and other attributes to improve their patients' satisfaction with care are not only promoting professionalism but also reducing their own risk for liability and malpractice. Physicians have a responsibility to stay current in their field[20] and to know when a patient's best interests are served by a referral to another physician or health care clinician.

TEAMWORK, STANDARDS, AND ACCOUNTABILITY

An interesting new aspect of professionalism is the increasing reliance on team approaches to medical care, as exemplified by physicians whose roles are defined by the location of their practice—historically in the intensive care unit or emergency department and now on the inpatient general hospital floor. Quality care requires coordination and effective communication across inpatient and outpatient sites among physicians who themselves may now typically work defined hours. This transition from reliance on a single, always available physician to a team, ideally with a designated coordinator, places new challenges on physicians, the medical care system, and the medical profession. Many teams comprise health care professionals who have complementary skills, including physicians, nurses, advanced practice providers, and pharmacists. This new model emphasizes the relevance of interprofessional education that focuses on core competencies, roles, responsibilities, communication, and teamwork.[21]

The changing medical care environment is also placing increasing emphasis on standards, outcomes, and accountability. As purchasers of insurance become more cognizant of value rather than just cost (Chapter 10), outcomes ranging from patients' satisfaction to rates of screening mammography (Chapter 183) and even to mortality rates with coronary artery bypass graft surgery (Chapter 59) have become metrics by which rational choices can be made. Clinical guidelines and critical pathways derived from randomized controlled trials and evidence-based medicine can potentially lead to more cost-effective care and better outcomes.

TABLE 1-1 PROFESSIONAL RESPONSIBILITIES

Commitment to:
- Professional competence
- Honesty
- Patient confidentiality
- Maintaining appropriate relationships
- Improving the quality of care
- Improving access to care
- Just distribution of finite resources
- Scientific knowledge
- Maintaining trust by managing conflicts of interest
- Professional responsibilities

From Brennan T, Blank L, Cohen J, et al. Medical professionalism in the new millennium: a physician charter. *Ann Intern Med*. 2002;1136:243-246.

SOCIAL JUSTICE

The importance of social justice acknowledges that the patient-physician interaction does not exist in a vacuum. The physician has a responsibility to the individual patient and to broader society to promote equitable access to health care, to eliminate disparities in health and health care delivery, and to bring science to even the most contentious political issues. For example, research into the relationship of firearms to rates of murder and suicide[22] can be useful for preventive medicine and public policy regardless of an individual's position on background checks and licensing for gun owners. The promotion of masks and vaccines to slow the COVID-19 pandemic was an example of how science should guide behaviors, even in times of uncertainty.

Medical schools,[23] medical research,[24] the medical profession,[25] and all medical institutions must embrace the principles of diversity, equity, inclusion, and social justice in education and the workplace. These principles optimize the profession's ability to mirror the populations it serves and to maximize the ability to address disparities and inequalities in care.

These major changes in many Western health care systems bring with them many risks and concerns. If the concept of limited choice among physicians and health care providers is based on objective measures of quality and outcome, channeling of patients to better providers is one reasonable definition of better selection and enlightened competition. If the limiting of options is based overwhelmingly on cost rather than measures of quality, outcomes, and patient satisfaction, physicians and their patients can be seriously disadvantaged.

Another risk is that the same genetic information that can lead to earlier diagnosis and to more effective, personalized medicine may be used against the very people whom it is supposed to benefit—by creating a stigma, potentially raising health insurance costs, or sometimes even making someone unable to obtain life or long-term care insurance. The ethical approach to medicine (Chapter 2), genetics (Chapter 31), and genetic counseling provides means to protect against this adverse effect of scientific progress.

BALANCING PROFESSIONAL RESPONSIBILITIES

In the modern environment, the physician often has a dual responsibility: to the health care system as an expert who helps create standards, measures of outcome, clinical guidelines, and mechanisms to ensure high-quality, cost-effective care; and to individual patients who entrust their well-being to that physician to promote their best interests within the reasonable limits of the system. A health insurance system that emphasizes cost-effective, value-based care, that gives physicians and health care providers responsibility for the health of a population and the resources required to achieve these goals, that must exist in a competitive environment in which patients can choose alternatives if they are not satisfied with their care, and that places increasing emphasis on health education and prevention can have many positive effects. In this environment, however, physicians must beware of overt and subtle pressures that could entice them to underserve patients and abrogate their professional responsibilities by putting personal financial reward ahead of their patients' welfare. The physician's responsibility to represent the patient's best interests and avoid financial conflicts by doing too little in the newer systems of capitated care provides different specific challenges but an analogous moral dilemma to the historical American system in which the physician is rewarded financially for doing too much.

An ongoing challenge for a profession that values dedication, attention to detail, and selflessness is the increasing risk of suffering burnout, which is characterized by emotional exhaustion and depersonalization. For example, the medical profession's heroic response to COVID-19, despite the personal health risks and significant psychological challenges, was inspiring. Nevertheless, the longer-term effects on physicians' resiliency will be a challenge to individual physicians and the profession as a whole.[26,27] Hopefully, both individual-focused and structural or organizational modifications in the work environment can result in clinically meaningful reductions in physician burnout.[28]

In the current health care environment, all health care professionals must strive to retain and expand their scientific knowledge base, redouble their commitment to the principles of their profession, and preserve their own well-being so they can serve others. In this spirit, *Goldman-Cecil Medicine* seeks to be a comprehensive approach to the ethos, foundation, and modern practice of internal medicine.

BIOETHICS IN THE PRACTICE OF MEDICINE

EZEKIEL J. EMANUEL

It commonly is argued that the bioethical dilemmas physicians face today result primarily from modern advances in medical technology. The rise of transplantation, intensive care units, genetics, implantable devices, and other technologies have created novel bioethical concerns. In reality, however, concerns about most medical ethical issues are as old as medicine itself. The Hippocratic Oath, composed around 400 BC, attests to the need of ancient Greek physicians for advice on how to address the many bioethical dilemmas that they confronted. The Oath addresses issues of confidentiality, abortion, euthanasia, sexual relations between physicians and patients, divided loyalties, and, at least implicitly, charity care and executions. Whether we agree with its advice or not, the mere existence of the Oath reminds physicians that medical ethical conundrums are inherent to medical practice. Technology may make these issues more common and change the context in which they arise, but many, if not most, bioethical issues that physicians regularly confront are age-old.

Many physicians are taught that four main principles can be invoked to address bioethical dilemmas: autonomy, nonmaleficence, beneficence, and justice. Autonomy is the idea that people should have the right and freedom to choose, pursue, and revise their own life plans. Nonmaleficence is the idea that people should not be knowingly harmed or injured. This principle is encapsulated in the oft-repeated phrase "first, do no harm"—*primum non nocere*. Beneficence refers to the positive actions that a physician should undertake to promote the well-being of his or her patients. In clinical practice, this obligation arises from the implicit and explicit commitments and promises central to the physician-patient relationship. Finally, the principle of justice is defined by the fair distribution of benefits and burdens that result from clinical interactions.

Although helpful in providing an initial framework, these principles are too broad to have more than limited value. The principles are also frequently underdeveloped and likely to conflict with each other, thereby resulting in bioethical dilemmas. The principles themselves do not offer guidance on how they should be balanced to resolve dilemmas. Given that they are focused on physician-patient encounters, the principles are also unhelpful when addressing bioethical issues at the system or institutional level, such as the allocation of scarce vaccines. Finally, these four principles are not comprehensive and fail to encapsulate all critical values. As the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) pandemic has made clear, other fundamental ethical principles and values include a focus on equity and priority to the worst off, duties to future generations, and professional integrity.[1]

There is no formula that can magically determine how to solve bioethical dilemmas.[2] Instead, medical professionals should follow an orderly analytic process. First, practitioners need to obtain the facts relevant to the situation. Second, they must delineate the fundamental bioethical issue. Third, they must identify all the crucial principles and values that relate to, and potentially conflict with, the case. Fourth, because many ethical dilemmas have been previously analyzed and subjected to empirical study, practitioners should examine the relevant literature so they may potentially identify new values, understand existing principles, reformulate the issue at hand, and see if there is an accepted resolution. Fifth, with this information, the practitioner must distinguish clearly unethical practices from a range of ethically permissible actions. Finally, it is important not only to come to a resolution but also to state clearly the justification for such decisions. Although unanimous decisions are ideal, the reality remains that such consensus may be elusive. Reasonable physicians must therefore take care to explain what principles they weighted highly and what interpretations they relied upon to resolve ethical dilemmas.

A multitude of bioethical dilemmas arise in medical practice each year, including issues of genetics, conscientious objection by providers, and termination of care. In clinical practice, the most common issues revolve around informed consent, termination of life-sustaining treatments, euthanasia and physician-assisted suicide, allocation of scarce resources (featured prominently during the SARS-CoV-2 pandemic and in transplantation), and conflict of interest.

PHYSICIAN-PATIENT RELATIONSHIP: INFORMED CONSENT

HISTORY

The requirement of informed consent dates as far back as Plato. The first recorded legal case on informed consent took place in England in 1767 when a patient complained that he had not given his consent for two surgeons to refracture his leg after it had healed improperly. The judge ultimately ruled that obtaining a patient's consent prior to a procedure was the "rule of the profession" and thus a legal obligation of surgeons. Failure to obtain consent, the court declared, was inexcusable. In more contemporary times, a landmark 1957 U.S. court ruling stated that physicians have a positive legal obligation to disclose information about risks, benefits, and alternative treatments to patients; this decision popularized the term *informed consent*.

DEFINITION AND JUSTIFICATION

Informed consent is a person's autonomous authorization to permit a physician—or other health professional—to undertake diagnostic or therapeutic interventions for himself or herself. The patient understands that he or she is taking responsibility for the decision while empowering someone else, the physician, to implement it. However, agreement to a course of medical treatment does not necessarily qualify as informed consent.

The four fundamental requirements for valid informed consent are: mental capacity, disclosure, understanding, and voluntariness. First, informed consent assumes that people have the mental capacity to make decisions; disease, development, or medications can compromise patients' mental capacity to provide informed consent. Adults are presumed to have the legal competence to make medical decisions, and whether an adult is incompetent to make medical decisions is a legal determination. Practically, physicians usually decide whether patients are competent based on whether they can understand the information disclosed, appreciate its significance for their own situation, and use logical and consistent thought processes in decision making. Incompetence in medical decision making does not mean a person is incompetent in all types of decision making and vice versa. Second, crucial information relevant to the decision must be disclosed, usually by the physician, to the patient. Third, the patient should understand the information and its implications for his or her interests and life goals. Finally, the patient's decision must be made voluntarily, without coercion or manipulation by the physician.

It is a mistake to view informed consent as a one-time event, such as the signing of a form. Informed consent is viewed more accurately as a process that evolves throughout the course of a patient's diagnosis and subsequent treatment.

Typically, a patient's autonomy is the value invoked to justify informed consent. Other values, such as bodily integrity and beneficence, have also been cited, especially in early legal rulings.

EMPIRICAL DATA

Extensive research on informed consent shows that physicians frequently do not communicate all the relevant information needed for patients to make an

An ongoing challenge for a profession that values dedication, attention to detail, and selflessness is the increasing risk of suffering burnout, which is characterized by emotional exhaustion and depersonalization. For example, the medical profession's heroic response to COVID-19, despite the personal health risks and significant psychological challenges, was inspiring. Nevertheless, the longer-term effects on physicians' resiliency will be a challenge to individual physicians and the profession as a whole.[26,27] Hopefully, both individual-focused and structural or organizational modifications in the work environment can result in clinically meaningful reductions in physician burnout.[28]

In the current health care environment, all health care professionals must strive to retain and expand their scientific knowledge base, redouble their commitment to the principles of their profession, and preserve their own well-being so they can serve others. In this spirit, *Goldman-Cecil Medicine* seeks to be a comprehensive approach to the ethos, foundation, and modern practice of internal medicine.

BIOETHICS IN THE PRACTICE OF MEDICINE

EZEKIEL J. EMANUEL

It commonly is argued that the bioethical dilemmas physicians face today result primarily from modern advances in medical technology. The rise of transplantation, intensive care units, genetics, implantable devices, and other technologies have created novel bioethical concerns. In reality, however, concerns about most medical ethical issues are as old as medicine itself. The Hippocratic Oath, composed around 400 BC, attests to the need of ancient Greek physicians for advice on how to address the many bioethical dilemmas that they confronted. The Oath addresses issues of confidentiality, abortion, euthanasia, sexual relations between physicians and patients, divided loyalties, and, at least implicitly, charity care and executions. Whether we agree with its advice or not, the mere existence of the Oath reminds physicians that medical ethical conundrums are inherent to medical practice. Technology may make these issues more common and change the context in which they arise, but many, if not most, bioethical issues that physicians regularly confront are age-old.

Many physicians are taught that four main principles can be invoked to address bioethical dilemmas: autonomy, nonmaleficence, beneficence, and justice. Autonomy is the idea that people should have the right and freedom to choose, pursue, and revise their own life plans. Nonmaleficence is the idea that people should not be knowingly harmed or injured. This principle is encapsulated in the oft-repeated phrase "first, do no harm"—*primum non nocere*. Beneficence refers to the positive actions that a physician should undertake to promote the well-being of his or her patients. In clinical practice, this obligation arises from the implicit and explicit commitments and promises central to the physician-patient relationship. Finally, the principle of justice is defined by the fair distribution of benefits and burdens that result from clinical interactions.

Although helpful in providing an initial framework, these principles are too broad to have more than limited value. The principles are also frequently underdeveloped and likely to conflict with each other, thereby resulting in bioethical dilemmas. The principles themselves do not offer guidance on how they should be balanced to resolve dilemmas. Given that they are focused on physician-patient encounters, the principles are also unhelpful when addressing bioethical issues at the system or institutional level, such as the allocation of scarce vaccines. Finally, these four principles are not comprehensive and fail to encapsulate all critical values. As the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) pandemic has made clear, other fundamental ethical principles and values include a focus on equity and priority to the worst off, duties to future generations, and professional integrity.[1]

There is no formula that can magically determine how to solve bioethical dilemmas.[2] Instead, medical professionals should follow an orderly analytic process. First, practitioners need to obtain the facts relevant to the situation. Second, they must delineate the fundamental bioethical issue. Third, they must identify all the crucial principles and values that relate to, and potentially conflict with, the case. Fourth, because many ethical dilemmas have been previously analyzed and subjected to empirical study, practitioners should examine the relevant literature so they may potentially identify new values, understand existing principles, reformulate the issue at hand, and see if there is an accepted resolution. Fifth, with this information, the practitioner must distinguish clearly unethical practices from a range of ethically permissible actions. Finally, it is important not only to come to a resolution but also to state clearly the justification for such decisions. Although unanimous decisions are ideal, the reality remains that such consensus may be elusive. Reasonable physicians must therefore take care to explain what principles they weighted highly and what interpretations they relied upon to resolve ethical dilemmas.

A multitude of bioethical dilemmas arise in medical practice each year, including issues of genetics, conscientious objection by providers, and termination of care. In clinical practice, the most common issues revolve around informed consent, termination of life-sustaining treatments, euthanasia and physician-assisted suicide, allocation of scarce resources (featured prominently during the SARS-CoV-2 pandemic and in transplantation), and conflict of interest.

PHYSICIAN-PATIENT RELATIONSHIP: INFORMED CONSENT

HISTORY

The requirement of informed consent dates as far back as Plato. The first recorded legal case on informed consent took place in England in 1767 when a patient complained that he had not given his consent for two surgeons to refracture his leg after it had healed improperly. The judge ultimately ruled that obtaining a patient's consent prior to a procedure was the "rule of the profession" and thus a legal obligation of surgeons. Failure to obtain consent, the court declared, was inexcusable. In more contemporary times, a landmark 1957 U.S. court ruling stated that physicians have a positive legal obligation to disclose information about risks, benefits, and alternative treatments to patients; this decision popularized the term *informed consent*.

DEFINITION AND JUSTIFICATION

Informed consent is a person's autonomous authorization to permit a physician—or other health professional—to undertake diagnostic or therapeutic interventions for himself or herself. The patient understands that he or she is taking responsibility for the decision while empowering someone else, the physician, to implement it. However, agreement to a course of medical treatment does not necessarily qualify as informed consent.

The four fundamental requirements for valid informed consent are: mental capacity, disclosure, understanding, and voluntariness. First, informed consent assumes that people have the mental capacity to make decisions; disease, development, or medications can compromise patients' mental capacity to provide informed consent. Adults are presumed to have the legal competence to make medical decisions, and whether an adult is incompetent to make medical decisions is a legal determination. Practically, physicians usually decide whether patients are competent based on whether they can understand the information disclosed, appreciate its significance for their own situation, and use logical and consistent thought processes in decision making. Incompetence in medical decision making does not mean a person is incompetent in all types of decision making and vice versa. Second, crucial information relevant to the decision must be disclosed, usually by the physician, to the patient. Third, the patient should understand the information and its implications for his or her interests and life goals. Finally, the patient's decision must be made voluntarily, without coercion or manipulation by the physician.

It is a mistake to view informed consent as a one-time event, such as the signing of a form. Informed consent is viewed more accurately as a process that evolves throughout the course of a patient's diagnosis and subsequent treatment.

Typically, a patient's autonomy is the value invoked to justify informed consent. Other values, such as bodily integrity and beneficence, have also been cited, especially in early legal rulings.

informed decision in clinical settings. The more complex the medical decisions, the more likely it is that physicians will obtain all the elements of informed consent.

Interestingly, data suggest that disclosure, both in informed consent documents and in discussion, is better in research than clinical settings, likely because of the research-specific requirement of having a written document to guide a process overseen by an independent committee, such as an institutional review board or a research ethics committee.

Patients frequently fail to recall crucial information disclosed during the process of obtaining informed consent, although they usually think they have sufficient information to make a decision. Whether patients fail to recall key information because they are overwhelmed by the information or because they find much of it not salient to their decision is unclear. The issue therefore lies more in determining what patients understand at the point of decision making, rather than what they recall later. For common medical interventions, such as elective surgery, the ideal informed consent would include the risks and benefits as quantified in randomized controlled trials, relevant data on the surgeon, the institution's clinical outcomes for the procedure, and a list of acceptable alternatives.[3]

Studies aimed at improving informed consent in clinical settings suggest that interactive media, such as interactive computer software and videos, improve patients' understanding of competing alternatives.[A1] Typically, patients who use a decision aid have greater knowledge of the evidence, feel more clear about what matters to them, have more accurate understanding of risks and benefits, and participate more in the decision-making process. Computer and web-based decision aids are now available for hundreds of common conditions and procedures.

A more modern challenge in obtaining informed consent is the introduction of electronic methods into the process, including smartphone applications in acute situations such as ischemic stroke.[A2] Digital models for informed consent often are not user-friendly for older patients, and evidence suggests that most people do not read click-through agreements on computers and mobile devices. Concern also exists that it may be challenging to obtain true voluntary choice without being able to assess the body language, tone, and emotion that can be observed during a person-to-person interaction.

One of the most important results of empirical research on informed consent is that there is a gap between the desire for information and the desire for actual decision making. Studies suggest that although most patients want information, far fewer actually want to make decisions about their own care. In one study, for example, only one third of patients desired decision-making authority, and patients' decision-making preferences were not correlated with their information-seeking preferences. Patients' preferences for decision-making authority generally increase with higher educational levels and decline with age. Most importantly, the more serious the illness, the more likely patients are to prefer that physicians make the decisions. Several studies suggest that patients who have less of a desire to make their own decisions generally are more satisfied with how the decisions are ultimately made.

PRACTICAL CONSIDERATIONS

Physicians who implement informed consent are usually concerned about the extent to which information should be disclosed and how to disclose it so it is well understood.[4] Physicians should disclose at least six fundamental elements of information to patients (Table 2-1). Because risk is usually a physician's principal concern, physicians also should disclose (1) the nature of the risks, (2) their magnitude, (3) the likelihood that the risks will occur, and (4) when the consequences might occur. Increasingly, these disclosures should include data both from clinical trials and from the institution and physician performing the test and treatments. In general, all serious risks, such as death, paralysis, stroke, infections, or chronic pain, even if rare, should be disclosed, as should common risks.

The key challenge in providing this information is doing so within reasonable time constraints and without overwhelming the patient with unnecessarily technical details. Fortunately, time constraints can be somewhat ameliorated by using interactive electronic media that allow patients to view information on their own schedules while facilitating the transfer of basic information.

The question of how much physicians should disclose is a state-level determination. Generally, states have adopted one of two divergent legal standards. The *physician* or *customary* standard, adapted from malpractice law, states that the physician should disclose all information "which a reasonable medical practitioner would make under the same or similar circumstances." Conversely, the *reasonable person* or *lay-oriented* standard states that physicians should disclose all information that a "reasonable person in the patient's circumstances would find material" to the medical decision. The physician standard is factual and can be determined empirically, but the patient-oriented standard, which is meant to engage physicians with patients, is hypothetical. Currently, each standard is used by about half of the United States.

The requirement of informed consent has no exceptions. In emergency situations, consent can be assumed under the belief that patients' interests are in survival and retaining maximal mental and physical functioning; as a result, reasonable persons would want treatment. In some circumstances, physicians may believe the process of informed consent could pose a serious psychological threat. In rare cases, the "therapeutic privilege" of promoting a patient's well-being trumps autonomy, but physicians should be wary of invoking this exception too readily.

If patients are deemed mentally incompetent to make medical decisions, family members—in order from spouse, children, parents, siblings, then more distant relatives—usually are selected as surrogates or proxies,[5] although there may be concerns about conflicting interests or knowledge of the patient's wishes. In the relatively rare circumstance in which a patient has formally designated a proxy, that person has decision-making authority.

The *substituted judgment* standard states that the proxy should choose what the patient would choose if he or she were competent. The *best interests* standard states that the proxy should choose what is best for the patient. However, it is often not clear what the patient would have decided, because the situation was not discussed with the patient and he or she left no advance care directive. Similarly, what is considered "best" for a patient can be controversial because of tradeoffs between quality of life and pure survival. These problems are complicated by the poor ability of many proxies to predict a patient's quality of life; proxies also tend to underestimate patients' future functional status and satisfaction. Similarly, a proxy's predictions on a mentally incapacitated patient's life-sustaining preferences are often inaccurate. In cases in which the patient is diagnosed with dementia, families tend to agree with patients on decisions regarding life-sustaining treatment two thirds of the time, better but not much better than the 50% agreement based on chance alone. Such confusion on how to decide for incapacitated patients can create conflicts among family members or between the family and medical providers. In such circumstances, an ethics consultation may be helpful.

TERMINATION OF MEDICAL INTERVENTIONS

HISTORY

Since the origins of medicine, withholding medical treatment from terminally ill patients while still providing palliative care, thereby allowing "nature to take its course," has been deemed ethical. Hippocrates argued that physicians should "refuse to treat those [patients] who are overmastered by their disease." In the 19th century, prominent American physicians advocated withholding cathartic and emetic "treatments" from the terminally ill. In 1900, the editors of *The Lancet* argued that physicians should intervene to ease the pain of death and that they did not have an obligation to prolong a clearly terminal life. The contemporary debate on terminating care began in the United States in 1976 with the *Quinlan* case, in which the New Jersey Supreme Court ruled that patients had a right to refuse life-sustaining interventions on the basis of a right to privacy, and that the family could exercise that right for a patient in a persistent vegetative state.

DEFINITION AND JUSTIFICATION

It generally is agreed that all patients have a right to refuse medical interventions. Ethically, this right is based on the patient's right to autonomy and is implied by the doctrine of informed consent. Legally, state courts have cited the right to privacy, the right to bodily integrity, and common law to justify the right to refuse medical treatment. In the 1990 *Cruzan* case, and in the subsequent physician-assisted suicide cases, the U.S. Supreme Court affirmed that there is a "constitutionally protected right to refuse lifesaving hydration and nutrition." The Court stated that "[A] liberty interest [based on the 14th Amendment] in refusing unwanted medical treatment may be inferred from

our prior decisions." All patients have both a constitutional and an ethical right to refuse medical interventions. These rulings were the basis of consistent state and federal court rulings in the *Schiavo* case to permit the husband to terminate artificial nutrition and hydration for his terminally ill wife in a vegetative state (Chapter 373).

EMPIRICAL DATA

Data show that termination of medical treatments is now the norm, and the trend has shifted toward stopping medical interventions based on the preferences of patients and their surrogate decision makers. Over 85% of Americans and 90% of decedents in intensive care units do not receive cardiopulmonary resuscitation. Of decedents in intensive care units, more than 85% die after the withholding or withdrawal of medical treatments, with an average of 2.6 interventions being withheld or withdrawn per decedent.

Despite extensive public support for use of advance care directives, passage of the Patient Self-Determination Act mandating that health care institutions inform patients of their right to complete such documents, and the 2016 policy to reimburse physicians for discussing end-of-life preferences with patients, less than 40% of Americans appear to have completed any written form of end-of-life decisions. Among Americans ages 75 and older, about 20% have neither written nor talked with someone about their wishes for medical treatment at the end of life. Data suggest that although over 40% of patients required active decision making about terminating medical treatments in their final days, more than 70% lacked actual decision-making capacity, thereby highlighting the importance of completing advance directives.

Efforts to improve completion of advance care directives have generated mixed results. In La Crosse County, Wisconsin, for example, after health care organizations in the county added an "Advance Directive" section to their electronic medical records, 90% of decedents had some type of advance directive. Unfortunately, successful pilot efforts like La Crosse County's have not been widely adopted or easily scaled. A persistent problem has been that even when patients complete advance care directives, the documents frequently are not readily available, physicians do not know they exist, or they tend to be too general or vague to guide decisions. The increasing use of electronic health records should make it possible for advance directives to be available whenever and wherever the patient presents to a health care provider. Although electronic health records will help in making existing advance directives available, they will not solve the problem of actually initiating a conversation among the physician, patient, and family about advance care planning. Starting that conversation still seems to be a persistent barrier.

Just as proxies are poor at predicting patients' wishes, data show that physicians are even worse at determining patients' preferences for life-sustaining treatments. In one study, for example, 30% of family conferences between clinicians and surrogates did not discuss preferences for end-of-life decision making for patients who were at high risk of death. In many cases, life-sustaining treatments are continued even when patients or their proxies desire them to be stopped. Conversely, many physicians discontinue or never begin interventions unilaterally without the knowledge or consent of patients or their surrogate decision makers. These discrepancies emphasize the importance of engaging patients early on in their care about treatment preferences.

PRACTICAL CONSIDERATIONS

Many practical considerations are applicable to enacting the right to terminate medical treatment (Table 2-2). First, patients have a right to refuse any and all medical interventions. The question of what medical interventions can be terminated—or not started—is a recurrent topic of debate. Courts have made clear that any treatment prescribed by a physician and administered by a health care provider can be stopped if it is more harmful than beneficial. The issue is not whether the treatment is ordinary, extraordinary, or heroic, or whether it is high-technology or low-technology. Treatments that can be stopped include not only ventilators, artificial nutrition, and hydration, but also dialysis, pacemakers, ventricular assist devices, antibiotics, and any medication.[6]

Second, there is no ethical or legal difference between withholding an intervention and withdrawing it. If a respirator or other treatment is started because physicians are uncertain whether a patient would have wanted it, they always can stop it later when information clarifies the patient's wishes. Although physicians and nurses might find stopping a treatment to be more difficult psychologically, withdrawal is ethically and legally permitted—and required—when it is consonant with the patient's wishes.

Third, competent patients have the exclusive right to make decisions about terminating their own care. If there is a conflict between a competent patient and his or her family, the patient's wishes are to be followed. It is the patient's right to refuse treatment, not the family's right. For mentally incompetent patients, the situation is more complex. If the patients left clear indications of their wishes, whether as explicit oral statements or as written advance directives, these wishes should be followed. Physicians should not be overly concerned about the precise form patients use to express their wishes; because patients have a constitutional right to refuse treatment, the focus should be whether the wishes are clear and relevant to the situation. If an incompetent patient did not leave explicit indications of his or her wishes or designate a proxy, the physician should identify a surrogate decision maker and rely upon that person's judgment. Some state courts have restricted what treatments a proxy decision maker can terminate, thereby requiring the incompetent patient to have given very specific instructions about the particular treatments he or she does not want to receive and the conditions under which care should be withheld or withdrawn. This requirement severely limits the authority and power of proxy decision makers.

Fourth, the right to refuse medical treatment does not translate into a right to demand any treatment, especially treatments that have no pathophysiologic rationale, have already failed, or are known to be harmful. Futility has become a justification to permit physicians unilaterally to withhold or withdraw treatments despite the family's requests for treatment. Some states, such as Texas, have enacted futility laws, which prescribe procedures by which physicians can invoke futility either to transfer a patient or to terminate interventions. However, the principle of futility is not easy to implement in medical practice. Initially, some commentators advocated that an intervention was futile when the probability of success was 1% or lower. This threshold seems to be based on empirical data, but it is a covert value judgment. Futility is meant to justify unilateral determinations by physicians, so it generally has been viewed as an inappropriate assertion that undermines physician-patient communication and violates the principle of shared decision making. Similar to the distinction between ordinary and extraordinary care, futility is increasingly viewed as more obfuscating than clarifying and is therefore being invoked much less often.

TABLE 2-2 PRACTICAL CONSIDERATIONS IN TERMINATION OF MEDICAL TREATMENTS

PRACTICAL QUESTION	ANSWER
Is there a legal right to refuse medical interventions?	Yes. The U.S. Supreme Court declared that competent people have a constitutionally protected right to refuse unwanted medical treatments based on the 14th Amendment.
What interventions can be legally and ethically terminated?	Any and all interventions (including respirators, antibiotics, pacemakers, ventricular assist devices, intravenous or enteral nutrition and hydration) can be legally and ethically terminated.
Is there a difference between withholding life-sustaining interventions and withdrawing them?	No. The consensus is that there is no important legal or ethical difference between withholding and withdrawing medical interventions. Stopping a treatment once begun is just as ethical as never having started it.
Whose view about terminating life-sustaining interventions prevails if there is a conflict between the patient and family?	The views of a competent adult patient prevail. It is the patient's body and life.
Who decides about terminating life-sustaining interventions if the patient is incompetent?	If the patient appointed a proxy or surrogate decision maker when competent, that person is legally empowered to make decisions about terminating care. If no proxy was appointed, there is a legally designated hierarchy, usually (1) spouse, (2) adult children, (3) parents, (4) siblings, and (5) available relatives.
Are advance care directives legally enforceable?	Yes. As a clear expression of the patient's wishes, they are a constitutionally protected method for patients to exercise their right to refuse medical treatments. In almost all states, clear and explicit oral statements are legally and ethically sufficient for decisions about withholding or withdrawing medical interventions.

ASSISTED SUICIDE AND EUTHANASIA

HISTORY

Even in Hippocrates' era, euthanasia and physician-assisted suicide were controversial issues. In 1905, a bill was introduced into the Ohio legislature to legalize euthanasia; it was defeated. In the mid-1930s, similar bills were introduced and defeated in the British Parliament and the Nebraska legislature. In 1997, the U.S. Supreme Court stated that there is no constitutional right to euthanasia or physician-assisted suicide, but that there also is no constitutional prohibition against states legalizing these interventions. As of 2021, nine U.S. states and the District of Columbia have legalized physician-assisted suicide—but no state has legalized euthanasia. The Montana Supreme Court did not recognize a constitutional right to physician-assisted suicide, but it ruled that the law permitting the termination of life-sustaining treatment protected physicians from prosecution if they helped hasten the death of a consenting, rational, terminally ill patient. Importantly, the American College of Physicians does not currently support the legalization of physician-assisted suicide. Both euthanasia and physician-assisted suicide are legal in many other countries, including the Netherlands, Belgium, Luxembourg, Canada, New Zealand, and Spain, and physician-assisted suicide is legal in Switzerland and Germany. Both euthanasia and physician-assisted suicide are illegal under English law.

DEFINITION AND JUSTIFICATION

The terms *euthanasia* and *physician-assisted suicide* require careful definition (Table 2-3). So-called passive and indirect euthanasia are misnomers and not actual instances of euthanasia; rather, they are ethical and legal ways to terminate care.

Four general arguments are made against permitting euthanasia and physician-assisted suicide. First, Kant and Mill, the philosophical champions of individual autonomy, believed that autonomy itself did not allow a person voluntarily to end conditions that made them autonomous. As a result, both philosophers were against voluntary enslavement and suicide. They therefore argued that the exercise of autonomy cannot include the ending of life, which would mean ending the possibility of exercising autonomy. Second, many dying patients may experience pain and suffering as the result of not receiving appropriate care. It is therefore possible that adequate care and pain management (Chapter 26) might relieve suffering without the need for euthanasia or physician-assisted suicide (Chapter 3). Although some patients may experience uncontrolled pain despite optimal end-of-life care, relatively few give pain as the justification for seeking euthanasia or physician-assisted suicide. Third, there is a clear ethical distinction between intentionally ending a life and terminating life-sustaining treatments. Both the motivations and physical acts are different. Injecting a life-ending medication, or providing a prescription for one, is not the same as removing or refraining from introducing a bodily invasive medical intervention. Finally, permitting euthanasia and physician-assisted suicide may introduce adverse consequences. For example, disturbing reports of involuntary euthanasia and euthanasia of depressed patients have come from the Netherlands and Belgium, and many worry about coercion of expensive or burdensome patients to accept euthanasia or physician-assisted suicide. Permitting euthanasia and physician-assisted suicide is likely to lead to further intrusions of lawyers, courts, and legislatures into the physician-patient relationship.

Four parallel arguments are forwarded to permit euthanasia and physician-assisted suicide. First, it is argued that autonomy justifies euthanasia and physician-assisted suicide. To respect autonomy requires permitting individuals to decide when and how it is better to end their lives. Second, beneficence—furthering the well-being of individuals—supports permitting euthanasia and physician-assisted suicide. In some cases, living can create more pain and suffering than death; ending a painful life relieves more suffering and produces a net good for the patient. Just the reassurance of having the option of euthanasia or physician-assisted suicide, even if not used, can provide "psychological insurance" and be beneficial to people. Third, euthanasia and physician-assisted suicide are no different from termination of life-sustaining treatments that are recognized as ethically justified. In both cases, the patient consents to die; in both cases, the physician intends to end the patient's life and takes some action to end the patient's life; and in both cases, the final result is the same: the patient's death. With no difference in the patient's consent, the physician's intention, or the final result, there can be no difference in the ethical justification. Fourth, the supposed slippery slope that would result from permitting euthanasia and physician-assisted suicide is unlikely. The idea that permitting euthanasia and physician-assisted suicide would undermine the physician-patient relationship or lead to forced euthanasia is completely speculative and not borne out by the available data.

TABLE 2-3 DEFINITIONS OF ASSISTED SUICIDE AND EUTHANASIA

TERM	DEFINITION
Voluntary active euthanasia	Intentional administration of medications or other interventions to cause the patient's death with the patient's informed consent
Involuntary active euthanasia	Intentional administration of medications or other interventions to cause the patient's death when the patient was competent to consent but did not consent (e.g., the patient may not have been asked)
Nonvoluntary active euthanasia	Intentional administration of medications or other interventions to cause the patient's death when the patient was incompetent and was mentally incapable of consenting (e.g., the patient might have been in a coma)
Passive euthanasia	Withholding or withdrawal of life-sustaining medical treatments from a patient to let him or her die (termination of life-sustaining treatments)—a poor term that should not be used
Indirect euthanasia	Administration of narcotics or other medications to relieve pain with the incidental consequence of causing sufficient respiratory depression to result in the patient's death
Physician-assisted suicide	A physician provides prescription medications or other interventions to a patient with the understanding that the patient can use them to commit suicide
Physician-assisted death	Either voluntary, active euthanasia or physician-assisted suicide. This term is preferred in the United States by advocates of these practices, but the term is not used in Europe.

EMPIRICAL DATA

Attitudes and practices related to euthanasia and physician-assisted suicide have been studied extensively. Two thirds of Americans say there are some situations in which a patient should be allowed to die, but 30% say that medical professionals should always do everything possible to save a patient's life. About 60% of adults think that these interventions are moral for a person who has an incurable disease and is suffering great pain with no hope of improvement. However, public support dramatically decreases to below 40% for patients who are ready to die because living is a burden or for patients who are burdensome to their families.

Physicians and medical societies tend to be much less supportive of euthanasia and physician-assisted suicide than the public,[7] with oncologists, palliative care physicians, and geriatricians among the least supportive. Among American and British physicians, the majority opposes legalizing either practice.

Approximately 25% of American physicians have received requests for euthanasia or physician-assisted suicide, including about 50% of oncologists and a growing number of neurologists.[8] Studies also indicate that less than 5% of American physicians have performed euthanasia or physician-assisted suicide. Surveys of oncologists indicate that about 4% have performed euthanasia and about 11% have performed physician-assisted suicide during their careers.

Safeguards for euthanasia and physician-assisted suicide are frequently violated. For example, one study found that about 55% of euthanasia requests came from the family. In about 40% of euthanasia and 20% of physician-assisted suicide cases, the patient was depressed; in only half of the cases was the request repeated, irrespective of treatment.

In Oregon and Washington state, over 70% of patients receiving physician-assisted suicide had cancer. Other characteristics strongly linked to requests for physician-assisted suicide included age over 65 years,[9] White race, more formal education, and having medical insurance.

Since physician-assisted suicide was legalized in Oregon over 20 years ago, less than 0.7% of all dying patients died by physician-assisted suicide. In the Netherlands and Belgium, where both euthanasia and physician-assisted suicide are legal, less than 5% of all deaths are by these measures, with 0.4 to 1.8% of all deaths as the result of euthanasia without the patient's consent.[10]

Counterintuitively, in all jurisdictions where it has been studied, pain is not the primary motivation for requesting euthanasia or physician-assisted suicide. In Oregon, loss of autonomy, dignity, and fear of being a burden are cited by patients as the predominant motives. In addition, psychological

A L G r a w a n y

distress, especially depression and hopelessness, seem to be more important than pain. Interviews with physicians and with patients with amyotrophic lateral sclerosis, cancer, or infection with human immunodeficiency virus show that pain is not associated with interest in euthanasia or physician-assisted suicide; instead, depression and hopelessness are the strongest predictors of interest. These findings raise important issues about the involvement of mental health experts in attempts to determine whether psychiatric treatment would change a patient's views.

Finally, data from the Netherlands and the United States suggest that there are problems in performing euthanasia and physician-assisted suicide. Dutch researchers reported that physician-assisted suicide causes complications in 7% of cases. Furthermore, the patients did not die, awoke from coma, or vomited up the medication in 15% of cases. Ultimately, in nearly 20% of physician-assisted suicide cases, the physician ended up injecting the patient with life-ending medication, converting physician-assisted suicide to euthanasia. These data raise serious questions about how to address complications of physician-assisted suicide when euthanasia is illegal or unacceptable.

PRACTICAL CONSIDERATIONS

There is widespread agreement that if euthanasia and physician-assisted suicide are used, they should be considered only after all reasonable attempts at physical and psychological palliation have failed.[11] A consensus—with slight differences—among American states and European countries has emerged on safeguards. These safeguards include: (1) the patient must be competent and must request euthanasia or physician-assisted suicide repeatedly and voluntarily; (2) in the Netherlands and other European countries, the patient must have unbearable pain or other suffering that cannot be relieved by optimal palliative interventions; by comparison, there is no requirement for unremitting suffering in the United States, but the patient must be terminally ill; (3) there should be a waiting period to ensure that the patient's desires are stable and sincere; and (4) the physician should obtain a second opinion from an independent physician. Although there have been some prosecutions in the United States, there have been no convictions—except for Dr. M. Jack Kevorkian in 1999—when physicians have participated in euthanasia and physician-assisted suicide.

ALLOCATION OF SCARCE MEDICAL RESOURCES

HISTORY

As with other medical ethical issues, decisions about the allocation of resources are not new. In 1792, Dominique Jean Larrey, Surgeon in Chief to Napoleon's Imperial Guard, devised a plan for sorting injured soldiers for emergency transport and medical treatment based on the severity of their wounds. During World War II, penicillin was finally produced in larger, but still quite limited quantities. Winston Churchill decided that priority for treatment should be given to soldiers who could be rapidly returned to active duty at the frontlines. Consequently, soldiers with sexually transmitted diseases were prioritized to receive penicillin over soldiers with severe wounds. Only a small fraction of the penicillin supply was allocated to civilians.

In the early 1960s, chronic renal dialysis was first developed in Seattle, Washington, but the number of machines was limited. To select which patients with chronic renal failure would receive dialysis, a committee used social value criteria, such as whether the person was employed, had dependents, or went to religious services. After publication of a *Life* magazine article about this so-called "God Committee," the process and criteria were roundly condemned. Eventually, Congress eliminated the allocation issue by funding all chronic renal dialysis through Medicare. Well before SARS-CoV-2 created the need to determine which patients should receive priority for ventilators and vaccines,[12] the most visible type of allocation decisions in the United States have been for solid organ transplantation, where demand for organs has regularly outstripped supply.

DEFINITION AND JUSTIFICATION

Rationing occurs in situations in which the supply of some resource (whether a medication, hospital bed, protective equipment, or operating room time) is insufficient to meet the needs of all patients who could medically benefit from the resource. Allocation or distribution is the process of determining which patients should receive priority in getting the medical resource.

Sometimes, an *absolute* scarcity of resources means that no matter how much money is spent, the supply will not be sufficient. Examples include the limited availability of organs for transplantation and, at least initially, vaccines and therapeutics for COVID. In some cases, the problem is a *relative* scarcity, where spending more money can eventually increase the supply of the resource but choices must be made in the meantime. An example was the supply of personal protective equipment or vaccines at points during the SARS-CoV-2 pandemic. Historically, many different criteria have been used for allocating scarce medical resources, including age, income, social usefulness (such as ability to fight in war), first come–first served, time on a waiting list, and medical urgency.

Fair allocation of scarce medical resources relies on four fundamental ethical values: (1) maximizing the benefits from the scarce resources, (2) treating people equally, (3) giving priority to the worst off, and (4) promoting and rewarding social value. Each of these can be interpreted and realized in at least two different ways (Table 2-4).

At least four important conclusions can be drawn about applying these ethical values and principles to allocating scarce medical resources. First, there is widespread agreement that an individual's wealth should not determine who receives scarce medical resources. Second, first come–first served should not be used because it almost invariably prioritizes people who live near medical facilities or who are wealthy and well-connected. Third, no single principle is sufficient to encapsulate all ethical values; a multi-principled allocation scheme will be required. Fourth, the combination of principles must be adopted to the particular medical situation. To save the most lives in the SARS-CoV-2 pandemic in the United States and Europe, for example, older individuals were prioritized for vaccines because they were the most likely to become severely ill and die if infected. For other illnesses, from which children are the most likely to die or transmit infections, younger people should be prioritized.

TABLE 2-4 ETHICAL VALUES FOR ALLOCATING SCARCE MEDICAL RESOURCES

VALUE	DEFINITION	PRINCIPLES OR DIFFERENT WAYS OF REALIZING THE VALUE	EXAMPLES
Maximizing benefit	Priority for resources should be given to individuals who have the best prospects of survival, as well as individuals who are likely to live for many more years if saved.	Save the most lives	Giving resources to individuals with the best chance of survival, disaster response
		Prognosis after treatment or save the most life years	Giving resources to the individuals predicted to survive the longest
Treating people equally	Nondiscrimination based irrelevant factors such as race or religion. Age can be a relevant factor if it influences prognosis or other value.	First come–first served	Time on a waiting list used in kidney transplantation
		Random selection or lottery	Selecting among otherwise equally qualified people (e.g., draft)
Giving priority to the worst off	Worst off can be defined as individuals who are sickest now or who have had the least of a critical good, such as the shortest life.	Sickest first	Severity score for liver transplantation
		Youngest first	Prioritized for influenza vaccine because they are integral to transmission
Promoting and rewarding social value	Giving resources to individuals who have helped or will help the most in the medical response.	Retrospective—reward individuals who contributed the most in the past	Prioritizes individuals who have donated organs or who have participated in prior medical research studies
		Prospective—reward individuals who are likely to contribute most in the future	Prioritize health care workers

EMPIRICAL DATA

Decisions about the allocation of medical resources are common, and different criteria are deployed in different circumstances. In the emergency department, for example, the fundamental allocation decision is which patients receive immediate attention. The primary allocation criterion used medical urgency rather than prognosis, so the sickest patient typically gets the most attention and preempts other patients. In SARS-CoV-2, priority for both personal protective equipment and vaccines was given to health care workers, who were socially useful because they could help save the lives of others, so as to follow the principle of maximizing benefit. After health care workers, the next priority for vaccines was older individuals, so as to maximize benefit by maximally reducing mortality.

The criteria for the transplantation of different organs emphasize different principles. For example, for liver transplantation (Chapter 140) the emphasis is on sickest patients, specifically those with the highest severity scores. This approach is controversial: it minimizes death on the waiting list but does not maximize lives saved with transplantation or the post-transplantation length of life saved. Conversely, in 2014, a new kidney transplant (Chapter 117) allocation scheme was introduced to emphasize the principle of prognosis or more life years by giving "higher quality" kidneys to patients with longer expected post-transplantation survival. This new approach retained the principle first come–first served but changed how "first-come" was determined. Rather than using time on the transplantation waiting list, the allocation scheme uses the time on dialysis to reduce racial and socioeconomic disparities, thereby emphasizing the principle of giving priority to the worst off. Although racial disparities have diminished, particularly for getting onto the waitlist, access disparities have persisted in part because poorer and minority patients may have barriers related to completing needed preoperative testing or receiving financial clearance.[13]

In the United States, reports on prioritizing limited SARS-CoV-2 vaccines (Chapter 337) generally invoked the principles of social usefulness and maximizing benefits by minimizing mortality. The resulting recommendations were to provide vaccines initially to health care workers and residents of long-term care facilities, with other groups prioritized by their risk of mortality (Table 2-5). Ultimately, however, the allocation was determined by individual states. For example, Florida extended the recommendations to include all persons ages 65 and older, as well as persons deemed by hospitals to be extremely vulnerable.

PRACTICAL CONSIDERATIONS

The process for implementing any allocation scheme typically has two stages. The first stage is to establish priority groups based upon the four ethical values. The second stage is to specify which priority group applies to each particular individual. For SARS-CoV-2, both stages were fulfilled. For organ transplantation, the national Organ Procurement and Transplantation Network establishes different criteria for determining priority groups, but then transplantation teams at each center determine which individual patients qualify to receive available organs based on the allocation criteria.

TABLE 2-5 ADVISORY COMMITTEE ON IMMUNIZATION POLICY'S INITIAL RECOMMENDATIONS FOR THE ALLOCATION OF COVID-19 VACCINES*

TIER OR PHASE	GROUPS RECOMMENDED	TOTAL PERSONS IN EACH GROUP (MILLIONS)
1a	Health care workers	21
	Residents of long-term care facilities	3
1b	Frontline essential workers (e.g., grocery store workers and police)	30
	Persons over age 75 years	19
1c	Persons ages 65-74 years	28
	Persons ages 16-64 years with high-risk medical conditions	81
	Essential workers not recommended for vaccination in Phase 1b (e.g., construction workers and bank tellers)	20
2	All persons over age 16 years not previously recommended	All others

*https://www.cdc.gov/mmwr/volumes/69/wr/pdfs/mm695152e2-H.pdf.

Each of these steps can be done less than ethically. The established priority groups may not adhere to the four key ethical values. For example, the decision by Florida's governor to open up initial allocation of SARS-CoV-2 vaccines for all people over age 65 years rather than for younger minority individuals with high-risk conditions was widely viewed as politically motivated. Another example is that wealthy patients often can pick organ transplant centers with shorter waiting lists or may be listed for organ transplantation at multiple centers. This ability to be listed multiple times favors the wealthy, who also can afford to be evaluated at multiple centers and fly to them when a suitable organ becomes available.

FINANCIAL CONFLICTS OF INTEREST

HISTORY

Worrying whether payment structures and fees compromise the integrity of medical decision making is not new. In 1899, a physician reported that more than 60% of surgeons in Chicago were willing to provide a 50% commission to physicians for referring cases. He subsequently argued that in some cases, this fee splitting led to unnecessary surgical procedures. A 1912 study by the American Medical Association confirmed that fee splitting was a common practice and it added to the list of physicians' financial conflicts of interest acts, which included selling patented medicines and patenting surgical instruments. In the 1990s, the ethics of pharmaceutical and biotech companies paying clinical researchers and physicians again raised the issue of financial conflicts of interest.

DEFINITION AND JUSTIFICATION

A conflict of interest occurs when a physician's secondary interests, such as making money, risks compromising or undermining a physician's primary interest, especially promoting a patient's well-being. Physicians not only have several primary interests (Table 2-6), they also have multiple secondary interests, such as earning income, raising a family, contributing to the profession, and pursuing avocational interests, such as hobbies. These secondary interests are not evil; typically, they are legitimate, even admirable. A conflict of interest occurs when one of these secondary interests could compromise pursuit of a primary interest, especially the patient's well-being.

Conflicts of interest are problematic because they can or appear to compromise the integrity of physicians' judgment, the patient's well-being, or the integrity of research. Conflicts of interest can induce a physician to do something—perform a procedure, fail to order a test, or distort data—that may not be in a patient's best interest. These conflicts can undermine the trust of both the patient and the public, not only in an individual physician but also in the medical profession at large.

Some people may believe in a distinction between actual and potential conflicts of interest, as well as claim that a conflict exists only when a physician's judgment is actually distorted or undermined. This distinction is wrong.[14] An actual conflict of interest occurs when a reasonable person could suspect that a physician's judgment could have been altered by the secondary interest. Appearances can be damaging, because it is difficult for patients and the public to determine what motives influence a physician's decision and it often is impossible to know whether judgment actually has been distorted. Financial conflicts of interest are of particular concern, not because they are worse than other types of conflicts, but because they are more pervasive, identifiable, and regulated compared with other conflicts. Since ancient times, the ethical norm has been clear: the physician's primary obligation is to the patient's well-being, and a physician's personal financial well-being comes second and should never compromise this duty.

EMPIRICAL DATA

Financial conflicts are common, and they are often underreported. The more imaging facilities and specialty referrals a practice has, the greater the utilization of medical services and the higher the health care spending—often without any benefit to the patients. In Florida, nearly 40% of physicians are owners of freestanding facilities to which they refer patients. In one study, 4 to 4.5

TABLE 2-6 PRIMARY INTERESTS OF PHYSICIANS

Promotion of the health and well-being of their patients
Advancement of biomedical knowledge through research
Education of future physicians and health care providers
Promotion of public health

times more imaging studies were ordered by self-referring physicians than by physicians who referred patients to radiologists. Similarly, urologists who had integrated radiation facilities into their practices increased their radiation use by 2.5 times compared with urologists who did not have such financial interests.

Similarly, multiple studies have shown that physicians' interaction with pharmaceutical representatives can lead to prescribing of new drugs, nonrational prescribing, and decreased use of generic drugs.[15] Industry funding for travel to continuing medical education symposia increases prescribing of the sponsor's drug. A study of 1400 FDA advisory committee members found that 13% had some financial interest in a drug company whose product was being reviewed by that committee; these members had a 63% chance of voting for its approval and an 84% chance of doing so if they sat on advisory boards for that company. A separate study found that 80% of U.S.-based hematologist-oncologists who use Twitter, often to tweet about pharmaceutical products, have at least one financial conflict of interest, with median payments of over $1000.

Regarding researcher conflicts of interest, the available data suggest that corporate funding does not appear to compromise the design and methodology of clinical research; in fact, commercially funded research may be methodologically more rigorous than government- or foundation-supported research. Conversely, data suggest that financial interests do distort researchers' interpretations and, most importantly, dissemination of research studies. Growing evidence suggests the suppression or selective publication of data unfavorable to corporate sponsors but the repeated publication of favorable results.

PRACTICAL CONSIDERATIONS

First, financial conflicts of interest are inherent in any profession in which the professional earns income from rendering a service. Second, conflicts come in many different forms, from legitimate payment for services rendered and ownership of medical laboratories and facilities, to drug company dinners, payment for attendance at pharmaceutical meetings, and consultation with companies.

Third, in considering how to manage conflicts, it is important to note that people are poor judges of their own potential conflicts. Individuals often cannot distinguish the various influences that guide their judgments, do not think of themselves as inherently bad, and do not imagine that payment shapes their judgments. Physicians tend to be defensive about charges of conflicts of interest. In addition, conflicts tend to act insidiously, subtly changing practice patterns so that they then become what appear to be justifiable norms.

Fourth, rules—whether laws, regulations, or professional standards—to regulate conflicts of interest are based on two considerations: (1) the likelihood that payment or other secondary interests would create a conflict, with greater financial interest tending to increase the risk of compromised judgment, and (2) the magnitude of the potential harm if judgment is compromised. Rules tend to be of three types: (1) disclosure of conflicts, (2) management of conflicts, and (3) outright prohibition. Federal law bans certain types of self-referral of physicians in the Medicare program. The American Medical Association and the Pharmaceutical Research and Manufacturers of America have established joint rules that permit physicians to accept gifts of minimal value but "refuse substantial gifts from drug companies, such as the costs of travel, lodging, or other personal expenses … for attending conferences or meetings." Additionally, the Physician Payment Sunshine Act, which was passed in 2010 as part of the Affordable Care Act and went into effect in August 2013, requires that drug and device manufacturers report all payments and transfers of value given to physicians to the Centers for Medicare and Medicaid Services so that such information can be published on a searchable public website.

Fifth, there is much emphasis on disclosure of conflicts, with the implicit idea being that sunshine is the best disinfectant. Disclosure may be useful in publications for peers, but it is unclear whether this is a suitable safeguard in the clinical setting. Disclosure may instead make patients worry more. Patients may have no context in which to place the disclosure or to evaluate the physician's clinical recommendation. Furthermore, self-disclosure often is incomplete, even when required.[16] Disclosure letters revealing a physician's financial conflicts of interest can significantly improve patients' knowledge of their physicians' financial relationships with the health care industry without adversely affecting patients' trust in their physicians or leading to missed appointments.[A3] Patients who are unsure about their physician's conflicts of interest report the least amount of trust in their physician, thereby suggesting the value of transparency.

Finally, some conflicts can be avoided by a physician's own action. Physicians can refuse to engage in personal investments in medical facilities or to accept gifts from pharmaceutical companies at relatively little personal cost. In other circumstances, the conflicts may be institutionalized, and minimizing them can occur only by changing the way organizations structure reimbursement incentives. Capitation encourages physicians to limit medical services, and its potentially adverse effects are likely to be managed by institutional rules rather than by personal decisions.

FUTURE DIRECTIONS

In the near future, as genetics moves ever more into the clinical setting, practicing physicians will frequently encounter ethical issues surrounding genetic testing, counseling, and treatment. The use of genetic tests without the extensive counseling so common in research studies would alter the nature of associated bioethical issues. Because these tests have serious implications for the patient and others, scrupulous attention to informed consent is essential. The bioethical issues raised by genetic tests for somatic cell changes, such as tests that occur commonly in cancer diagnosis and risk stratification, are no different from the issues raised with the use of any laboratory or radiographic test.

In some cases, ethics consultation services may be of assistance in resolving bioethical dilemmas. However, data suggest that consultation services are used mainly for problems that arise in individual cases and are not used for more institutional or policy problems.

3 PALLIATIVE CARE

ROBERT M. ARNOLD AND JEAN S. KUTNER

By 2030, 20% of the U.S. population will be older than 65 years, and people older than 85 years constitute the fastest growing segment of the population. Owing to successes in public health and medicine, many of these people will live the last years of their lives with chronic medical conditions such as cirrhosis, end-stage kidney disease, heart failure, chronic obstructive pulmonary disease (COPD), and dementia. Even human immunodeficiency virus (HIV) and many cancers, once considered terminal, have turned into chronic diseases. More recently, palliative care has taken an important role in the care of hospitalized patients with coronavirus disease-2019 (COVID-19) infection (Chapter 337), many of whom qualify for palliative care because of underlying prior conditions, severity of acute illness, or both.[1]

The burden associated with these illnesses and their treatments is high. Chronically ill patients report multiple physical and psychological symptoms that lower their quality of life. The economic pressures associated with medical care adversely affect patients' socioeconomic status and cause family stress, especially among caregivers who spend 20 or more hours a week helping their loved ones.

Palliative care, which was developed to decrease the burden associated with chronic illness, emphasizes patient- and family-centered care that optimizes quality of life by anticipating, preventing, and treating suffering. Palliative care throughout the continuum of illness addresses physical, intellectual, emotional, social, and spiritual needs while facilitating the patient's autonomy, access to information, and choice.

Palliative care is both a subspeciality and a key component of good medicine. Specialty palliative care, delivered by an interdisciplinary team, is available concurrently with or independently of curative or life-prolonging care. Palliative and nonpalliative health care providers should collaborate and communicate

times more imaging studies were ordered by self-referring physicians than by physicians who referred patients to radiologists. Similarly, urologists who had integrated radiation facilities into their practices increased their radiation use by 2.5 times compared with urologists who did not have such financial interests.

Similarly, multiple studies have shown that physicians' interaction with pharmaceutical representatives can lead to prescribing of new drugs, nonrational prescribing, and decreased use of generic drugs.[15] Industry funding for travel to continuing medical education symposia increases prescribing of the sponsor's drug. A study of 1400 FDA advisory committee members found that 13% had some financial interest in a drug company whose product was being reviewed by that committee; these members had a 63% chance of voting for its approval and an 84% chance of doing so if they sat on advisory boards for that company. A separate study found that 80% of U.S.-based hematologist-oncologists who use Twitter, often to tweet about pharmaceutical products, have at least one financial conflict of interest, with median payments of over $1000.

Regarding researcher conflicts of interest, the available data suggest that corporate funding does not appear to compromise the design and methodology of clinical research; in fact, commercially funded research may be methodologically more rigorous than government- or foundation-supported research. Conversely, data suggest that financial interests do distort researchers' interpretations and, most importantly, dissemination of research studies. Growing evidence suggests the suppression or selective publication of data unfavorable to corporate sponsors but the repeated publication of favorable results.

PRACTICAL CONSIDERATIONS

First, financial conflicts of interest are inherent in any profession in which the professional earns income from rendering a service. Second, conflicts come in many different forms, from legitimate payment for services rendered and ownership of medical laboratories and facilities, to drug company dinners, payment for attendance at pharmaceutical meetings, and consultation with companies.

Third, in considering how to manage conflicts, it is important to note that people are poor judges of their own potential conflicts. Individuals often cannot distinguish the various influences that guide their judgments, do not think of themselves as inherently bad, and do not imagine that payment shapes their judgments. Physicians tend to be defensive about charges of conflicts of interest. In addition, conflicts tend to act insidiously, subtly changing practice patterns so that they then become what appear to be justifiable norms.

Fourth, rules—whether laws, regulations, or professional standards—to regulate conflicts of interest are based on two considerations: (1) the likelihood that payment or other secondary interests would create a conflict, with greater financial interest tending to increase the risk of compromised judgment, and (2) the magnitude of the potential harm if judgment is compromised. Rules tend to be of three types: (1) disclosure of conflicts, (2) management of conflicts, and (3) outright prohibition. Federal law bans certain types of self-referral of physicians in the Medicare program. The American Medical Association and the Pharmaceutical Research and Manufacturers of America have established joint rules that permit physicians to accept gifts of minimal value but "refuse substantial gifts from drug companies, such as the costs of travel, lodging, or other personal expenses … for attending conferences or meetings." Additionally, the Physician Payment Sunshine Act, which was passed in 2010 as part of the Affordable Care Act and went into effect in August 2013, requires that drug and device manufacturers report all payments and transfers of value given to physicians to the Centers for Medicare and Medicaid Services so that such information can be published on a searchable public website.

Fifth, there is much emphasis on disclosure of conflicts, with the implicit idea being that sunshine is the best disinfectant. Disclosure may be useful in publications for peers, but it is unclear whether this is a suitable safeguard in the clinical setting. Disclosure may instead make patients worry more. Patients may have no context in which to place the disclosure or to evaluate the physician's clinical recommendation. Furthermore, self-disclosure often is incomplete, even when required.[16] Disclosure letters revealing a physician's financial conflicts of interest can significantly improve patients' knowledge of their physicians' financial relationships with the health care industry without adversely affecting patients' trust in their physicians or leading to missed appointments.[A3] Patients who are unsure about their physician's conflicts of interest report the least amount of trust in their physician, thereby suggesting the value of transparency.

Finally, some conflicts can be avoided by a physician's own action. Physicians can refuse to engage in personal investments in medical facilities or to accept gifts from pharmaceutical companies at relatively little personal cost. In other circumstances, the conflicts may be institutionalized, and minimizing them can occur only by changing the way organizations structure reimbursement incentives. Capitation encourages physicians to limit medical services, and its potentially adverse effects are likely to be managed by institutional rules rather than by personal decisions.

FUTURE DIRECTIONS

In the near future, as genetics moves ever more into the clinical setting, practicing physicians will frequently encounter ethical issues surrounding genetic testing, counseling, and treatment. The use of genetic tests without the extensive counseling so common in research studies would alter the nature of associated bioethical issues. Because these tests have serious implications for the patient and others, scrupulous attention to informed consent is essential. The bioethical issues raised by genetic tests for somatic cell changes, such as tests that occur commonly in cancer diagnosis and risk stratification, are no different from the issues raised with the use of any laboratory or radiographic test.

In some cases, ethics consultation services may be of assistance in resolving bioethical dilemmas. However, data suggest that consultation services are used mainly for problems that arise in individual cases and are not used for more institutional or policy problems.

3 PALLIATIVE CARE

ROBERT M. ARNOLD AND JEAN S. KUTNER

By 2030, 20% of the U.S. population will be older than 65 years, and people older than 85 years constitute the fastest growing segment of the population. Owing to successes in public health and medicine, many of these people will live the last years of their lives with chronic medical conditions such as cirrhosis, end-stage kidney disease, heart failure, chronic obstructive pulmonary disease (COPD), and dementia. Even human immunodeficiency virus (HIV) and many cancers, once considered terminal, have turned into chronic diseases. More recently, palliative care has taken an important role in the care of hospitalized patients with coronavirus disease-2019 (COVID-19) infection (Chapter 337), many of whom qualify for palliative care because of underlying prior conditions, severity of acute illness, or both.[1]

The burden associated with these illnesses and their treatments is high. Chronically ill patients report multiple physical and psychological symptoms that lower their quality of life. The economic pressures associated with medical care adversely affect patients' socioeconomic status and cause family stress, especially among caregivers who spend 20 or more hours a week helping their loved ones.

Palliative care, which was developed to decrease the burden associated with chronic illness, emphasizes patient- and family-centered care that optimizes quality of life by anticipating, preventing, and treating suffering. Palliative care throughout the continuum of illness addresses physical, intellectual, emotional, social, and spiritual needs while facilitating the patient's autonomy, access to information, and choice.

Palliative care is both a subspeciality and a key component of good medicine. Specialty palliative care, delivered by an interdisciplinary team, is available concurrently with or independently of curative or life-prolonging care. Palliative and nonpalliative health care providers should collaborate and communicate

ABSTRACT

Palliative care, which was developed to decrease the burden associated with chronic illness, emphasizes patient- and family-centered care that optimizes quality of life by anticipating, preventing, and treating suffering. It is both a subspecialty and a key component of good medical care for seriously ill patients. Palliative care should be delivered throughout the course of a patient's illness—from diagnosis through death. The specialty involves a multidisciplinary group of clinicians who work with the patients' primary clinicians to provide an extra layer of support. When caring for patients with serious illness, good palliative care requires that the following questions be addressed: (1) is the patient's care consistent with his or her goals; (2) is the patient physically comfortable or psychologically suffering; and (3) is the family suffering.

KEYWORDS

palliative care

advance directives
living wills
quality of life

about care needs while focusing on peace and dignity throughout the course of illness, during the dying process, and after death.

Given that most seriously ill patients are not seen by a palliative care subspecialist, every clinician should have basic competency in palliative care. For example, all primary care clinicians should know the basic tenets of treating pain (Chapter 26) as well as how to discuss advance directives (Chapter 2) and give "bad" news. Specialties with a high prevalence of seriously ill patients, such as critical care, cardiology, pulmonology, neurology, nephrology, and oncology, should have more advanced skills.[2–5] Interventions to promote both specialty and primary palliative care are associated with improvements in the patient's burden of symptoms and reductions in the utilization of acute care services, although its effects on quality of life and on the caregiver are less consistent.[A1-A4]

Six points deserve special emphasis. First, palliative care can be delivered at any time during the course of an illness and is often provided concomitantly with disease-focused, life-prolonging therapy. For example, most elderly patients with chronic incurable illnesses, who might benefit from palliative care, are in the last 10 years of their lives but do not consider themselves to be dying. Moreover, prognostication is an inexact science (E-Fig. 3-1). If palliative care is to have an impact on patients' lives, it should be integrated into patients' treatment plans early in the illness. The strongest data for early integration of specialty palliative care is from patients early in the course of oncologic disease.[6,A5] Second, although the specialty of palliative care has grown exponentially over the past 25 years, most patients with serious illness will never see a palliative care specialist because of shortages in the palliative care workforce. Some of the shortages may be addressed by telehealth,[7] but data on palliative care delivered this way are inconclusive.[A6] All clinicians must integrate palliative care principles if the care of seriously ill patients is to be improved. Third, palliative care primarily focuses on the burden of illness rather than treating the disease itself. Because these burdens can be physical, psychological, spiritual, or social, good palliative care requires a transdisciplinary approach. Fourth, palliative care takes the family unit (however defined by the patient) as the central focus of care. Treatment plans thus must be developed for both the patient and the family. Given data on prolonged grief disorder, treatment should continue for the family after the patient's death. Fifth, palliative care recognizes that medical treatments do not uniformly reverse the progression of disease and that patients die. At some point in a patient's illness, the treatments may be associated with more risks and cause more burden than benefit. Palliative care recognizes this reality and starts with a discussion of the patient's goals and the development of an individualized treatment plan that is consistent with these goals. Finally, disparities in palliative care mirror the inequities in health care generally.[8] Black patients have poorer symptom management, fewer discussions of goals of care, and less access to hospice.[A7] In addition, Black physicians receive less palliative care training and rate their training in palliative care as less good than their general medical education.

Many people confuse palliative care with hospice—an understandable confusion because hospice epitomizes the palliative care philosophy. The two, however, are different. In the United States, hospice services and eligibility criteria are largely driven by the Medicare Hospice Benefit. Although exceptions exist, hospice in the United States provides palliative care, primarily at home, for patients who have a life expectancy of 6 months or less and who are willing to forgo life-prolonging treatments. However, the requirement that patients must have a life expectancy of 6 months or less limits hospice's availability, as does the requirement that patients relinquish potentially life-prolonging treatments. Moreover, because doctors often are unwilling to cease these treatments until very late in the disease course, so are most patients.

PALLIATIVE CARE DOMAINS

Palliative care is a philosophy of and approach to care that addresses physical, psychological, spiritual, existential, social, and ethical domains. When caring for patients with chronic life-limiting illness, good palliative care requires that the following questions be addressed.

IS THE PATIENT PHYSICALLY COMFORTABLE?

Across many chronic conditions, patients have a large number of inadequately treated physical symptoms (Table 3-1). The reasons are multifactorial and range from inadequate education of the clinician, to societal beliefs regarding the inevitability of suffering in chronic illness, to concerns regarding opioids, to the lack of evidence-based treatments in noncancer patients.

The first step to improve symptom management is a thorough assessment. Standardized instruments such as the Brief Pain Inventory (Fig. 3-1) measure both the patient's symptoms and the effect of those symptoms on the patient's life. Use of standardized instruments (such as the Edmonton Symptom Assessment Scale [E-Fig. 3-2]) ensures that clinicians will identify overlooked or underreported symptoms and, as a result, will enhance the satisfaction of both the patient and family.

The evidence for the treatment of end-stage symptoms continues to improve. For example, palliative care can improve quality of life in patients with end-stage heart failure,[A8] who often require such help.[9] The use of nonsteroidal anti-inflammatory agents and opioids can result in effective pain management in more than 75% of patients with cancer. Advances such as intrathecal pumps and neurolytic blocks are helpful in the remaining 25% (Chapter 26). Medical marijuana, while popular, has little impact on cancer pain.[A9] The use of oxygen is not helpful for refractory dyspnea except when hypoxia has been documented, whereas use of medications for depression often can be helpful in addressing refractory dyspnea (Chapter 362). Recent data also suggest that prophylactic subcutaneous scopolamine butylbromide decreases dying patients' death rattle.[A10]

IS THE PATIENT PSYCHOLOGICALLY SUFFERING?

Patients may be physically comfortable but still suffering. Psychological symptoms and syndromes such as depression, delirium, and anxiety are common in patients with life-limiting or chronic illnesses. It may be difficult to determine whether increased morbidity and mortality are caused by the physical effects of the illness or by the psychological effects of depression and anxiety on energy, appetite, or sleep. Screening questions focusing on mood (e.g., "Have you felt down, depressed, and hopeless most of the time for the past 2 weeks?") and anhedonia (e.g., "Have you found that little brings you pleasure or joy in the past 2 weeks?") have been shown to help in diagnosing depression in this population. Increasing data show that treatment of depression in chronic illness is possible and improves both morbidity and mortality.

For patients and families facing mortality, existential and spiritual concerns are common. Progressive illness often raises questions of love, legacy, loss, and meaning. A clinician's role is not to answer these questions or to provide reassurance, but rather to understand concerns of the patient and family, how they are coping, and what resources might help. Spirituality often is a source of comfort, and clinicians can ascertain a patient's beliefs using a brief instrument such as the FICA Spiritual Assessment Tool (Table 3-2). A single screening question such as "Are you at peace?" may identify patients who are in spiritual distress and facilitate referrals to chaplains.

IS THE FAMILY SUFFERING?

Families, defined broadly as those individuals who care most for the patient, are an important source of support for most patients. Families provide informal caregiving, often at the expense of their own physical, economic, and psychological health. Good palliative care requires an understanding of how the family is coping and a search for ways to provide family members with the social or clinical resources they need to improve their well-being. Comprehensive and individually targeted interventions can reduce the burden on caregivers, although the absolute benefits are relatively small.

Because patients who are receiving palliative care often die, the treating team must address bereavement and family suffering after death. Good communication and informational brochures about receiving care in an intensive care unit can decrease family members' adverse psychological outcomes after death.[A11] A letter of condolence or a follow-up phone call to the next of kin after a patient's death is respectful and offers the opportunity to clarify questions about the patient's care. Some family members suffer from complicated grief—a recently described syndrome associated with separation and traumatic distress, with symptoms persisting for more than 6 months. Primary care clinicians, who have ongoing relationships with the loved one, and hospices, which provide bereavement services for a year after the patient's death, have the opportunity to assess whether the grief symptoms persist or worsen.

IS THE PATIENT'S CARE CONSISTENT WITH THE PATIENT'S GOALS?

The *sine qua non* for palliative care is ensuring that the treatment plan is consistent with the patient's goals and values. Some patients prefer longevity over quality of life, but a large proportion of elderly, seriously ill patients are not focused on living as long as possible. Instead, they want to maintain a sense of control, relieve their symptoms, improve their quality of life, avoid being a burden on their families, and have a closer relationship with their loved ones.

Ensuring that treatment is consistent with a patient's goals requires good communication skills (Table 3-3). The approaches to giving bad news, discussing goals of care, and talking about forgoing life-sustaining treatment have similar structures.[10] First, the patient needs to understand the basic facts about the

TABLE 3-1 APPROACHES TO THE MANAGEMENT OF PHYSICAL AND PSYCHOLOGICAL SYMPTOMS

SYMPTOM	ASSESSMENT	TREATMENT
Pain	How severe is the symptom (as assessed with the use of validated instruments) and how does it interfere with the patient's life? What is the etiology of the pain? Is the pain assumed to be neuropathic or somatic? What has the patient used in the past (calculate previous days' equal analgesic dose)?	Prescribe medications to be administered on a standing or regular basis if pain is frequent. Consider alternative medicine, concomitant analgesics, and interventional treatments for pain to minimize the use of opiates. Concomitant analgesics (e.g., corticosteroids, anticonvulsants, tricyclic antidepressants, and bisphosphonates) should be used when applicable (particularly for neuropathic pain). For mild pain: use acetaminophen or a nonsteroidal anti-inflammatory agent. For moderate pain: titrate short-acting opioids (see Table 26-6). For severe pain: rapidly titrate short-acting opioids until pain is relieved or intolerable side effects develop; start long-acting opiates once pain is controlled. Rescue doses: prescribe immediate-release opioids—10% of the 24-hour total opiate every hour (orally) or every 30 minutes (parenterally) as needed.
Constipation	Is the patient taking opioids?	Prescribe laxatives for all patients on opiates, starting with a stimulant laxative. If ineffective, add drugs from alternative classes (e.g., stimulant, osmotic laxatives, and enemas). Prescribe methylnaltrexone if still constipated.
Shortness of breath	Ask the patient to assess the severity of the shortness of breath. Does the symptom have reversible causes?	Prescribe oxygen to treat hypoxia-induced dyspnea, but *not* if the patient is not hypoxic. Cardiopulmonary rehabilitation decreases dyspnea and improves exercise tolerance. Opioids may relieve breathlessness without measurable reductions in respiratory rate or oxygen saturation; effective doses are often lower than those used to treat pain. Aerosolized opioids do not work. Fans or cool air decrease dyspnea. Use reassurance, relaxation, distraction, cognitive behavioral therapy, and massage therapy.
Fatigue	Is the patient too tired for activities of daily living? Is the fatigue secondary to depression? Is a disease process causing the symptom or is it secondary to reversible causes?	Provide cognitive education about conserving energy use. Treat underlying conditions appropriately and as consistent with patient's goals and values. Psychostimulants may help in selected diseases for limited time periods.
Nausea	Which mechanism is causing the symptom (e.g., stimulation of the chemoreceptor trigger zone, gastric stimulation, delayed gastric emptying or "squashed stomach" syndrome, bowel obstruction, intracranial processes, or vestibular vertigo)? Is the patient constipated?	Prescribe an agent directed at the underlying cause (Chapter 118). If persistent, give antiemetic around the clock. Multiple agents directed at various receptors or mechanisms may be required.
Anorexia and cachexia	Is a disease process causing the symptom, or is it secondary to other symptoms (e.g., nausea and constipation) that can be treated? Is the patient troubled by the symptom or is the family worried about what not eating means?	A nutritionist may help find foods that are more appetizing (Chapter 13). Provide counseling about the prognostic implications of anorexia (Chapter 200).
Delirium	Is the cause reversible? Is the confusion acute, over hours to days? Does consciousness wax and wane? Is there a problem of attention? Does the patient have disorganized thinking? Does the patient have an altered level of consciousness—either agitated or drowsy?	Identify underlying causes and manage symptoms (Chapter 361). Recommend behavioral therapies, including avoidance of excess stimulation, frequent reorientation, and reassurance. Ensure presence of family caregivers and explain delirium to them. Although antipsychotics are often used, the data are meager.
Depression	Over the last 2 weeks, have you been bothered (0) not at all, (1) several days, (2) more than half the days, (3) every day by: • Little interest or pleasure in doing things • Feeling down, depressed, or hopeless	Add the points for each answer. For a score >2, further evaluation is recommended, with consideration of supportive psychotherapy, cognitive approaches, behavioral techniques, pharmacologic therapies (see Table 362-5), or a combination of these interventions. Prescribe psychostimulants for rapid treatment of symptoms (within days) or selective serotonin reuptake inhibitors, which may require 3 to 4 weeks to take effect; tricyclic antidepressants are relatively contraindicated because of their side effects.
Anxiety (applicable also for family members)	Over the last 2 weeks, have you been bothered (0) not at all, (1) several days, (2) more than half the days, (3) every day by: • Feeling nervous, anxious, or on edge • Not being able to stop or control worrying	Add the points for each answer. A score of >2 should lead to a more in-depth evaluation (see Chapter 362) and consideration of supportive counseling and benzodiazepines or selective serotonin reuptake inhibitors (Table 362-9).
Spiritual distress	Are you at peace?	Inquire about spiritual support. Offer chaplain support.

Modified from Morrison RS, Meier DE. Palliative care. *N Engl J Med*. 2004;350:2582-2590.

diagnosis, possible treatments, and prognosis. The communication skill that helps clinicians communicate information is *Ask-Tell-Ask*—exploring what the patient knows or wants to know, then explaining or answering questions, and then providing an opportunity for the patient to ask more. In the hospital, where discontinuity of care is common and misunderstandings frequent, it is important to determine what the patient knows before providing information so as to keep everyone well-coordinated. When giving serious news, knowing what the patient already knows allows the clinician to anticipate the patient's reaction. Finally, information must be titrated based on the patient's preferences. Although most patients want to hear everything about their disease, a minority do not. There is no foolproof way to ascertain what any patient wants to know other than by asking.

When giving patients information, it is important to give small pieces of information, not to use jargon, and to confirm that patients understand what they have been told.[A12] Clinicians should focus on the key message the patient should hear (the headline) rather than overwhelming the patient with

biomedical information. Giving information is like titrating medication dosing: one gives information, checks understanding, and then gives more information based on what the patient has heard.

After ensuring that the doctor and the patient have a shared understanding of the medical facts, clinicians should engage in an open-ended conversation about the patient's goals as the disease progresses. This strategy requires that the patient be asked about both hopes and fears. One might ask: "Given the medical situation, as you think about the future, what brings you joy and pleasure?" "If your time is limited, what are the things that are most important to achieve?" "What are your biggest fears or concerns?" "As you think about the future, what do you want to avoid or not have the doctors do?" The clinician can use an understanding of these goals to make recommendations about which treatments to provide and which treatments would not be helpful. As a result, palliative care provided early in the trajectory of illness can improve quality of life, mood, and even survival.

FIGURE 3-1, cont'd.

Clinicians often find that talking about prognosis is particularly difficult for two reasons: first, it is hard to foretell the future accurately; and second, they fear this information will "take away patients' hope." Thus, clinicians often avoid talking to patients about these issues unless specifically asked. Although some patients do not want to hear prognostic information, for many patients, this information helps them plan their lives. Patients who are told that their disease is generally terminal are more likely to spend a longer period of time enrolled in hospice and avoid aggressive treatment at the end of life, without adverse psychological consequences. Furthermore, their families usually have fewer post-death adverse psychological outcomes.

Given that one cannot guess how much information to provide, a clinician can start these conversations by asking, "Are you the kind of person who wants to hear about what might happen in the future with your illness or would you rather take it day by day?" If the patient requests the latter, the clinician can follow up by asking if there is someone else with whom he or she can talk about the prognosis. Second, before giving prognostic information, it is useful to inquire about the patient's concerns in order to provide information in the most useful manner. Finally, it is appropriate when discussing prognostic information to acknowledge uncertainty: "The course of this cancer can be quite unpredictable, and we don't have a crystal ball. I think you should be aware of the possibility that your health may deteriorate quickly, and you should plan accordingly. We probably are dealing with weeks to months, although some patients do better, and some do worse. Over time, the course may become clearer, and if you wish, I may be able to be a little more precise about what we are facing." A structured handout and conversational format, called Best Case/

TABLE 3-2 FICA SPIRITUAL ASSESSMENT TOOL

F—What is your **faith**/religion? Do you consider yourself a religious or spiritual person? What do you believe in that gives meaning/importance to life?

I—**Importance** and **influence** of faith. Is your faith/religion important to you? How do your beliefs influence how you take care of yourself? What are your most important hopes? What role do your beliefs play in regaining your health? What makes life most worth living for you? How might your disease affect this?

C—Are you part of a religious or spiritual **community**? Is this of support to you, and how? Is there a person you really love or is very important to you? How is your family handling your illness? What are their reactions/expectations?

A—How would you like me to **address** these issues in your health care? What might be left undone if you were to die today? Given the severity or chronicity of your illness, what is most important for you to achieve? Would you like me to talk to someone about religious/spiritual matters?

From Puchalski C, Romer A. Taking a spiritual history. *J Palliat Med*. 2000;3:129-137.

TABLE 3-3 CORE COMMUNICATION SKILLS

RECOMMENDED SKILL	EXAMPLE
A. IDENTIFYING CONCERNS AND RECOGNIZING CUES	
Elicit Concerns	
Open-ended questions	"Is there anything you wanted to talk to me about today?"
Active listening	Allowing patient to speak without interruption; allowing pauses to encourage patient to speak
Recognize Cues	
Informational concerns	Patient: "I'm not sure about the treatment options"
Emotional concerns	Patient: "I'm worried about that"
B. RESPONDING TO INFORMATIONAL CONCERNS	
"Ask-tell-ask"	Topic: communicating information about cancer stage
Ask	"Have any of the other doctors talked about what stage this cancer is?"
Tell	"That's right, this is a stage IV cancer, which is also called metastatic cancer…"
Ask	"Do you have questions about the staging?"
C. RESPONDING TO EMOTIONAL CONCERNS	
Nonverbal Empathy: S-O-L-E-R	
S	Face the patient **S**quarely
O	Adopt an **O**pen body posture
L	**L**ean toward the patient
E	Use **E**ye contact
R	Maintain a **R**elaxed body posture
Verbal Empathy: N-U-R-S-E	
N	**N**ame the emotion: "You seem worried"
U	**U**nderstand the emotion: "I see why you are concerned about this"
R	**R**espect the emotion: "You have shown a lot of strength"
S	**S**upport the patient: "I want you to know that I will still be your doctor whether you have chemotherapy or not"
E	**E**xplore the emotion: "Tell me more about what is worrying you"
D. DISCUSSING GOALS OF CARE	
R	**R**eframe that the status quo is not working: "I worry that more treatment will hurt you more than help"
E	**E**xpect emotion: "I can see this is not what you wanted to hear"
M	**M**ap the patient values: "Have you ever filled out a living will?" "Given the medical situation, what brings you joy and meaning?" "As you look at the future, what do you want to avoid?"
A	**A**lign with the patient values: "What I am hearing you say is…."
P	**P**ropose a plan

Adapted from Back AL, Arnold RM, Tulsky JA. *Discussing Prognosis*. Alexandria, VA: American Society of Clinical Oncology; 2008.

Worst Case, has been extensively used in surgery and nephrology,[11] both to discuss prognosis and as a way to discuss treatment alternatives (E-Fig. 3-3).

The clinician must discuss these topics in an empathic way. Palliative care conversations are as much about emotions as facts. Talking about disease progression or death may elicit negative emotions such as anxiety, sadness, or frustration. These emotions decrease a patient's quality of life and interfere with the ability to hear factual information. Empathic responses strengthen the patient-physician relationship, increase the patient's satisfaction, and make the patient more likely to disclose other concerns. The first step is recognizing when the patient is expressing emotions. Once the clinician recognizes the emotion being expressed, he or she can respond empathically.

It is also important for clinicians to recognize their own emotional reactions to these conversations. The physician's emotional reactions color impressions of the patient's prognosis, thereby making it hard to listen to the patient, and may influence the physician to hedge bad news. The clinician should become aware of her or his own emotional reactions to ensure that the conversation focuses on the patient rather than the health care provider's needs.

In addition to good communication skills, palliative care requires a basic knowledge of medical ethics and the law. For example, patients have the moral and legal right to refuse any treatment, even if refusal results in their death. There is no legal difference between withholding and withdrawing life-sustaining treatment. Differences in state laws regarding physician-assisted dying (Chapter 2), as well as use of agents such as medical marijuana or psychedelics, require clinicians to stay current regarding local legislation. When confronted with areas of ambiguity, the clinician should know how to obtain either a palliative care or ethics consultation.

During the past 50 years, a societal push has encouraged patients to designate health care proxies and to create advance care planning documents, typified by the use of living wills.[12] These documents are meant to protect patients against unwanted treatments and to ensure that as they are dying, their wishes are followed. Unfortunately, there are few empirical data showing that these documents actually change practice. Still, discussions of the documents with health professionals and family members generally provoke important conversations about end-of-life care decisions and may help families confronted with difficult situations know they are respecting their loved one's wishes.[13]

IS THE PATIENT GOING TO DIE IN THE LOCATION OF CHOICE?

Most patients say that they want to die at home. Unfortunately, most patients die in institutions—either hospitals or nursing homes. Burdensome transitions decrease quality in end-of-life care. Good palliative care requires establishing a regular system of communication to minimize transitional errors. A social worker who knows about community resources is important in the development of a dispositional plan that respects the patient's goals.

Hospice programs are an important way to allow patients to die at home. In the United States, *hospice* refers to a specific, government-regulated form of end-of-life care, available under Medicare since 1982 but subsequently adopted by Medicaid and many other third-party insurers. Hospice care typically is provided at home, a nursing home, or specialized acute care unit. Care is provided by an interdisciplinary team, which usually includes a physician, advanced practice provider, nurse, social worker, chaplain, volunteers, bereavement coordinator, and home health aides, all of whom collaborate with the primary care clinician, patient, and family. Bereavement services are offered to the family for a year after the death.

Hospices are paid on a per diem rate and are required to cover all the costs related to the patient's life-limiting illness. Because of this and the fact that the focus of hospice is on comfort rather than life prolongation, many hospices will not cover expensive treatments such as inotropic agents in heart failure or chemotherapy in cancer, even if they have a palliative effect. Not surprisingly, many hospices are experimenting with different service models that do not require patients to forgo possibly life-prolonging treatments, in an attempt to enroll patients earlier in the course of their illness and increase access to their services. The Veterans Administration and some insurance plans cover hospice services concurrently with disease-focused therapies.

Hospice care for nursing home residents is associated with less aggressive care near death but an overall increase in Medicare expenditures. By comparison, interdisciplinary palliative care for hospitalized adults with serious illness can reduce costs.[14]

4 DISPARITIES IN HEALTH AND HEALTH CARE

JOHN Z. AYANIAN

Disparities in health care and health are evident in all countries around the world. Health disparities often reflect a country's specific history, such as the legacy of conquest and colonization for American Indians and of slavery, segregation, and structural racism for Black Americans. Socioeconomic disparities in health related to poverty or lack of education occur globally and can be reduced by better educational and economic opportunities and by effective health care systems and social services.

Most efforts to understand and reduce health disparities have focused on race, ethnicity, and socioeconomic status and have sought to disentangle the relative impact of health care, health behaviors, and biologic, social, and environmental factors as contributors to these disparities. More recently, these efforts have expanded to assess a wider range of health disparities, including those faced by sexual minorities, people with disabilities, and people in disadvantaged urban or rural areas.

DEFINITIONS OF HEALTH DISPARITY AND HEALTH EQUITY

The U.S. Department of Health and Human Services defines a health disparity as a "health difference that is closely linked with economic, social, or environmental disadvantage." Conversely, health equity is defined as the "attainment of the highest level of health for all people."[1] These definitions build on U.S. National Academy of Medicine reports in which equitable health care was defined as "care that does not vary in quality due to personal characteristics, such as gender, ethnicity, geographic location, or socioeconomic status" and which identified racial and ethnic disparities in health care as an important contributor to disparities in health outcomes. Fragmented systems of care and structural racism, as well as bias and discrimination on the part of health professionals, can contribute to differential receipt of health care services, thereby leading to health disparities. However, not all differences in health care represent unacceptable disparities related to discrimination, in part because some differences in care may be related to clinical appropriateness or patients' preferences.

DEMOGRAPHIC CHANGES IN THE U.S. POPULATION

The racial and ethnic composition of the U.S. population has changed substantially in recent decades. As the population has grown from 193 million in 1965 to 332 million in 2022, almost half of this growth related to nearly 60 million new immigrants. During this time period, the non-Hispanic White proportion of the U.S. population dropped from 84 to 60% and the Black proportion rose from 11 to 13%. In contrast, the Hispanic proportion grew substantially from 4 to 18% and the Asian or Pacific Islander proportion increased from 1 to 6%. These trends are projected to continue through 2065, when the corresponding proportions of the U.S. population are projected to be 46% non-Hispanic White, 13% Black, 24% Hispanic, and 14% Asian or Pacific Islander if current immigration patterns persist.

RACIAL AND ETHNIC DISPARITIES IN HEALTH OUTCOMES

Substantial differences in life expectancy between Black and White Americans have narrowed since 1975 as life expectancy has risen.[2] Notably, as of 2018, life expectancy was about 3 years longer for Hispanic individuals relative to White individuals. In contrast, life expectancy in 2018 was 4 years shorter for Black individuals, relative to White individuals (Fig. 4-1). Overall, the all-cause mortality rate is about 25% higher in Black Americans. In 2020, coronavirus disease 2019 (COVID-19; Chapter 336) was the third leading cause of death in the United States. COVID-19 death rates have been disproportionately higher in Black and Hispanic populations, predominately because of higher infection rates rather than higher case-fatality rates.[3] As a result, during the COVID-19 pandemic in 2020, life expectancy declined from 2018 by 3.88 years for Hispanic Americans and 3.25 years for Black Americans, compared with 1.36 years for White Americans.[4] These disparities underscore the disproportionate effect that COVID-19 has had on Hispanic and Black adults.

Heart disease and cancer are the two leading causes of death for all five racial and ethnic groups officially designated by the U.S. federal government, but age-adjusted death rates for specific causes vary substantially by race and ethnicity (Table 4-1). Black Americans have the highest age-adjusted death rates, overall and due specifically to heart disease[5] and to cancer, followed by non-Hispanic White Americans. Black Americans also have the highest

ABSTRACT

Life expectancy in the United States varies substantially by race, ethnicity, and socioeconomic status. Relative to other racial and ethnic groups, Black Americans have the highest death rates overall and due to heart disease and cancer—the two most common causes of death in the United States. American adults with low incomes have substantially shorter life expectancy than more affluent adults, and the magnitude of this disparity differs widely among U.S. geographic areas. These differences arise from differences in health risk factors such as smoking and hypertension, as well as disparities in insurance coverage and access to care. The increasing diversity of the U.S. population has created new challenges and opportunities for health care providers and organizations to serve patients from diverse backgrounds by addressing interpersonal bias and discrimination, as well as the fragmented systems of care that lead to health care disparities. Trained interpreters improve care for patients with limited English proficiency, and coordinated care especially benefits disadvantaged patients by reducing fragmentation. Health care organizations should implement reporting systems to monitor disparities in the quality and outcomes of care, set measurable goals for reducing disparities, and encourage programs to meet these goals.

TABLE 4-1 AGE-ADJUSTED DEATH RATES FOR 10 LEADING CAUSES OF DEATH BY RACE/ETHNICITY IN THE UNITED STATES, 2018*

	ALL PERSONS	WHITE, NON-HISPANIC	BLACK OR AFRICAN AMERICAN	HISPANIC OR LATINO	ASIAN OR PACIFIC ISLANDER	AMERICAN INDIAN OR ALASKA NATIVE
All causes	723.6	745.7	852.9	524.1	390.6	571.8
Heart disease	163.6	167.5	203.7	112.3	85.0	110.8
Cancer	149.1	154.4	168.7	107.4	92.6	97.2
Chronic lung disease	39.7	45.0	29.6	17.0	11.6	28.3
Cerebrovascular disease	37.1	35.9	50.8	32.0	29.4	24.2
Alzheimer disease	30.5	32.2	26.6	25.5	15.8	15.3
Diabetes mellitus	21.4	18.8	37.6	24.6	16.4	31.0
Poisoning	19.3	23.6	19.0	11.1	3.3	19.6
Influenza and pneumonia	14.9	15.0	15.8	11.7	12.8	13.7
Suicide	14.2	18.0	7.0	7.4	6.9	13.7
Kidney disease	12.9	11.6	24.8	11.6	8.3	11.4

*Per 100,000 population, from *Health, United States, 2019*. Hyattsville, MD: National Center for Health Statistics; 2020. https://www.cdc.gov/nchs/data/hus/2019/005-508.pdf.

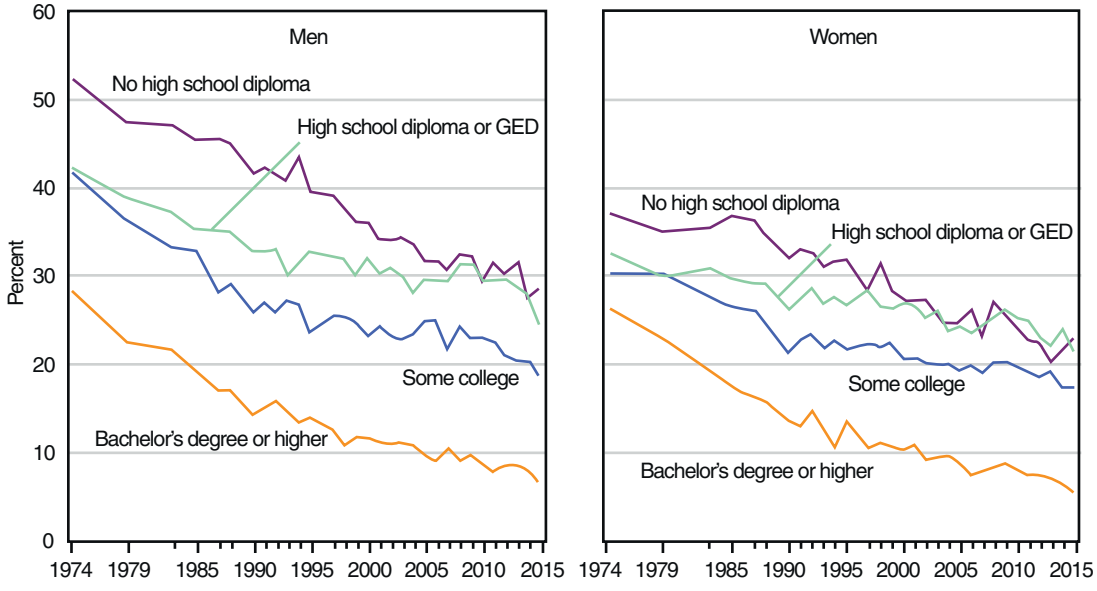

FIGURE 4-2. **Current cigarette smoking: adults aged 25+. Note: Smoked 100 cigarettes in their lifetime and now smoke every day or some days. (Source: NCHS, *Health, United States, 2016*, Figure 10 and Table 48. Data from the National Health Interview Survey [NHIS].)**

death rates from cerebrovascular disease, diabetes mellitus, and kidney disease, but lower-than-average death rates from chronic lung disease, poisoning, and suicide. Non-Hispanic White Americans, in contrast, have higher-than-average death rates from these latter three causes.

Hispanic Americans have lower-than-average death rates from all causes except diabetes mellitus (see Table 4-1). American Indians have lower-than-average death rates from most causes except diabetes mellitus and poisoning, but they also have markedly elevated death rates from chronic liver disease (27.7 deaths per 100,000 vs. 11.1 among all persons). Asian and Pacific Islander Americans together have lower-than-average death rates from each of the 10 leading causes of death, including markedly lower rates for heart disease, cancer, chronic lung disease, Alzheimer disease, poisoning, and suicide.

Major health risk factors that contribute to morbidity and mortality among adults vary substantially by race, ethnicity, and level of education.[6] Black adults have the highest age-adjusted prevalence of hypertension (43%; Chapter 64), which is a major contributor to their high rates of heart disease, cerebrovascular disease, and kidney disease, whereas the prevalence of hypertension is substantially lower among non-Hispanic White (29%), Hispanic (28%), and Asian (27%) adults. In contrast, the prevalence of diabetes mellitus is substantially higher among Black (18%), Mexican American (18%), and Asian (16%) adults than among non-Hispanic White adults (10%).[7]

Smoking rates (Chapter 363) vary widely in the United States by race/ethnicity and sex. Rates are highest among non-Hispanic White men (21%), Black men (22%), and American Indian men (28%) and women (24%). Smoking rates are intermediate among non-Hispanic White women (19%), Black women (14%), Hispanic men (16%), and Asian men (15%), and they are lowest among Hispanic women (7%) and Asian women (5%).[8]

SOCIOECONOMIC DISPARITIES IN HEALTH OUTCOMES

Socioeconomic gradients in morbidity and mortality, which are a major component of health disparities, have widened in the United States in recent years. Adults with higher educational levels and incomes have experienced substantial gains in life expectancy related to their lower smoking rates and better control of hypertension, hyperlipidemia, and other chronic health conditions and risk factors. By comparison, adults with low incomes experienced minimal gains overall prior to COVID-19.[9] For example, socioeconomic status is an independent correlate of mortality after a myocardial infarction.[10] Among middle-aged non-Hispanic White adults without postsecondary education, life expectancy has actually decreased since 1999 as a result of rising death rates from alcohol-related liver disease, drug overdoses, and suicide, and overall U.S. life expectancy has decreased since 2014.[11]

U.S. smoking rates have declined substantially since 1974, with the steepest drop among college graduates (Fig. 4-2). Higher smoking rates among less educated adults remain a major contributor to socioeconomic disparities in morbidity and mortality. The temporal improvement in smoking rates overall

has been offset by marked increases in age-adjusted death rates due to drug overdoses—particularly among non-Hispanic White adults, who have had a three-fold increase in this death rate from 1999 to 2015 primarily due to opioid overdoses (Fig. 4-3).[12]

The magnitude of socioeconomic disparities in mortality vary widely by geographic region within the United States. When considering life expectancy at age 40, for example, adults with incomes in the lowest quartile can expect to survive to age 81 years in New York City and several California cities, but only to age 77 years in some cities in Ohio, Indiana, and Michigan. These disparities in life expectancy are primarily related to regional differences in the prevalence of behavioral and metabolic risk factors, including smoking, limited physical activity, obesity, hypertension, and diabetes mellitus. Among high-income counties, cancer has become the leading cause of death, whereas heart disease remains the leading cause in poorer counties.

INSURANCE COVERAGE AND ACCESS TO CARE

Health insurance coverage is an important contributor to racial, ethnic, and socioeconomic disparities in health care and health outcomes, especially for adults who are under age 65 years and do not have near-universal insurance coverage through Medicare, as do older adults.[13] Since the Affordable Care Act was enacted in 2010, 38 states have expanded Medicaid to nonelderly adults with annual incomes below 138% of the federal poverty level (<$17,775 for a single adult in 2021). In all states, adults with incomes of 100 to 400% of the federal poverty level (about $12,900 to $51,500 in 2021) have become eligible for subsidized private insurance.

With this expanded coverage, rates of uninsurance have declined substantially for poor and near-poor adults in all racial and ethnic groups since 2010 (Fig. 4-4), although they still remain substantially higher for Hispanic and Black adults (Fig. 4-5).

Health insurance is a primary determinant of access to care because it reduces financial barriers to preventive services such as smoking cessation and cancer screening and to effective care for chronic health conditions such as hypertension, diabetes, and heart disease. Uninsured adults are three to five times more likely to delay or forgo needed care or prescription medications because of cost than are adults with private insurance or Medicaid (Fig. 4-6). Gaining insurance coverage is associated with improved access to care and better health outcomes, particularly for middle-aged adults with low incomes and chronic health conditions such as hypertension and diabetes mellitus. Life expectancy is also correlated with the local availability of physicians, especially primary care doctors, but also to a lesser degree specialists as well.[14]

QUALITY OF CARE

An extensive body of research has documented substantial racial and ethnic disparities in the quality of health care provided to patients with a wide range of major conditions, including heart disease, hypertension, diabetes mellitus, kidney disease, breast cancer, and colorectal cancer. Relative to non-Hispanic

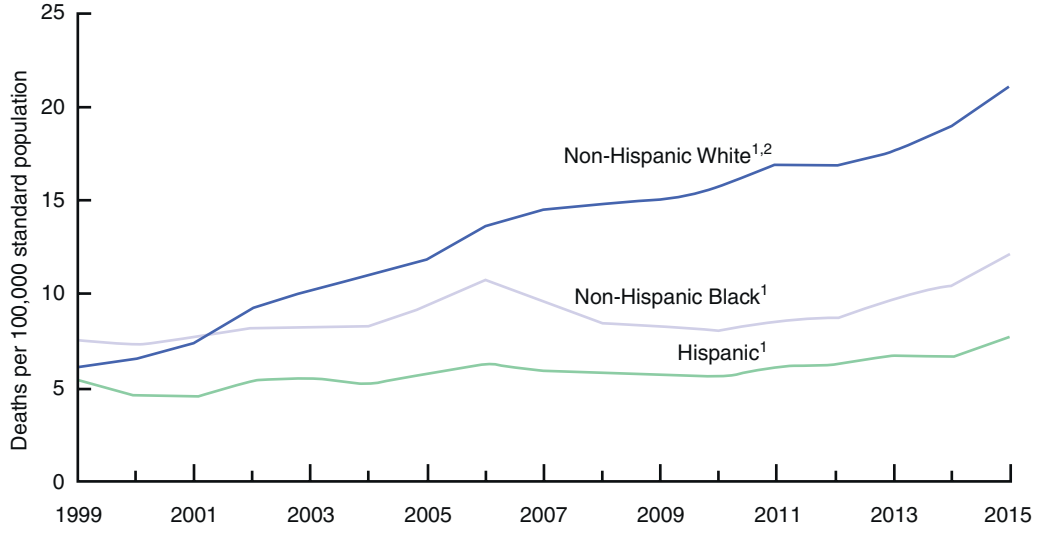

FIGURE 4-3. Age-adjusted drug overdose death rates by race and ethnicity: United States, 1999-2015. [1]Significant increasing trend, $p < 0.005$. [2]Rate for non-Hispanic White persons was significantly higher than for non-Hispanic Black and Hispanic persons, $p < 0.001$. Notes: Deaths are classified using the *International Classification of Diseases, Tenth Revision*. Drug overdose deaths are identified using underlying cause-of-death codes X40-X44, X60-X64, X85, and Y10-Y14. Deaths for Hispanic persons may be underreported by about 5%. Access data table for Figure 3 at: https://www.cdc.gov/nchs/data/databriefs/db273_table.pdf#3. (Source: Hedegaard H, Warner M, Miniño AM. *Drug overdose deaths in the United States, 1999–2015*. FIGURE 4-5. **Percentage of adults aged 18 to 64 who were uninsured at the time of interview, by race and ethnicity: United States, 2010-2018.** Note: Data are based on household interviews of a sample of the civilian noninstitutionalized population. (Source: NCHS, National Health Interview Survey, 2010-2018, Family Core Component.)

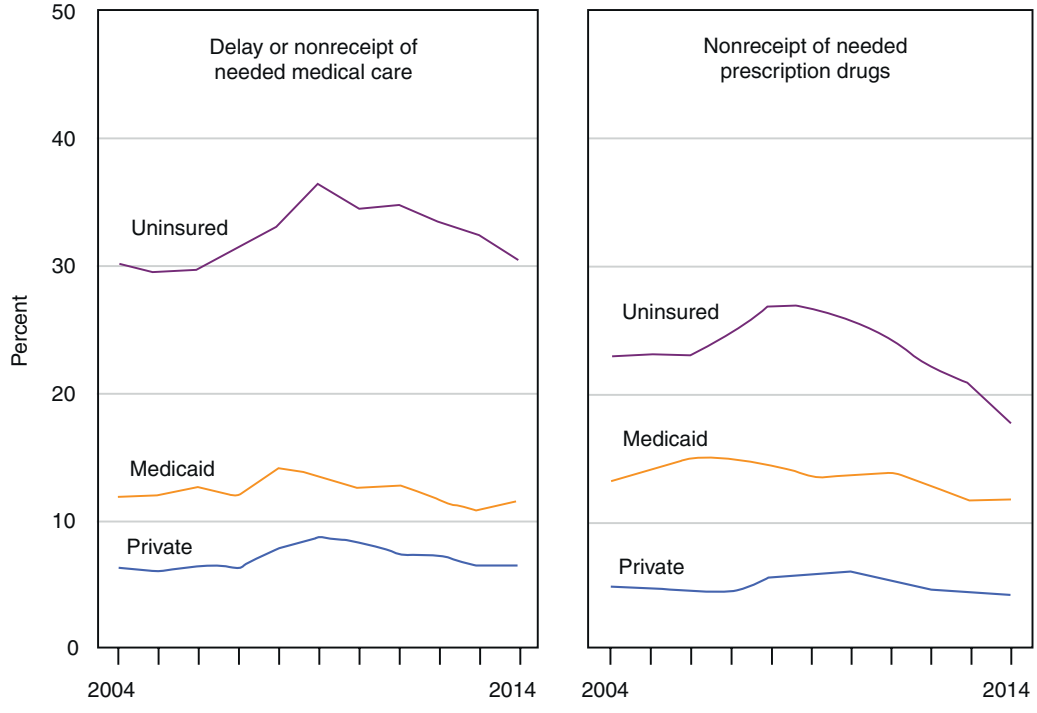

FIGURE 4-6. **Difficulty accessing care: Adults aged 18 to 64.** (Source: CDC/NCHS, Health, United States, 2015, Figure 12 and Table 63. Data from the National Health Interview Survey [NHIS].)

White adults, Black and Hispanic adults are much less likely to have good control of their hypertension or diabetes mellitus. These disparities are narrowed among Medicare enrollees nationally, and they have been eliminated in Medicare health maintenance organizations in the western United States. Over time, such improvements in the control of hypertension and diabetes mellitus may further reduce disparities in cardiovascular mortality for Black Americans relative to other racial and ethnic groups.

Similar improvements have been noted in the quality of hospital care nationally for minority patients with acute myocardial infarction, heart failure, and pneumonia, for whom the quality of hospital care is now clinically equivalent by race and ethnicity. Most notably, substantial disparities in timely percutaneous coronary interventions (Chapter 57) and in rates of influenza and pneumococcal vaccination (Chapter 15) have been eliminated for Black and Hispanic patients relative to non-Hispanic White patients.

CLINICAL APPROACHES TO REDUCE DISPARITIES

The increasing diversity of the U.S. population has created new challenges and opportunities for health care professionals and organizations to meet the needs of patients from diverse backgrounds, particularly immigrants. The federal Office of Minority Health has produced national standards for delivering culturally and linguistically appropriate health care, including the use of trained interpreters for patients with limited English proficiency. The principal standard is that health care providers should ensure quality care and services that are effective, equitable, understandable, respectful, and responsive to diverse cultural health beliefs and practices, preferred languages, health literacy, and other communication issues. Physicians and other caregivers who have undergone educational programs in cultural competencies may provide better care to diverse populations. However, this training has not clearly improved

ALGranady

patients' outcomes, such as reducing disparities in control of glycemia, blood pressure, or cholesterol for Black adults with diabetes mellitus.

Disparities in health care often arise from fragmented systems of care, particularly for conditions that require complex services, such as cancer, cardiovascular disease, end-stage renal disease, and organ transplantation. When care requires multiple specialists or sites of care, disparities also can be reduced by emphasizing patient-centered approaches that provide better coordinated care with enhanced support for patients from disadvantaged backgrounds, such as those who are uninsured or have less education or limited English proficiency. This support may include multidisciplinary team-based care and enhanced outreach to patients and their families via care coordinators, patient navigators, and community health workers.[15]

It is also essential for clinical leaders in health care organizations to implement reporting systems (e.g., through enhanced electronic health records) to identify and monitor disparities related to race, ethnicity, language, and socioeconomic factors. These systems can be used to set measurable goals for reducing disparities in the quality and outcomes of care, motivate quality improvement programs to address clinically important disparities, and assess progress toward achieving these goals.

5 GLOBAL HEALTH

ALI H. MOKDAD

Efforts to improve health and reduce death and disability in populations across the world require a comprehensive understanding of what disables and kills people across countries, time, age, and sex. Before the coronavirus disease 2019 (COVID-19) pandemic, global life expectancy was increasing despite marked disparities among and often within countries. The COVID-19 pandemic is estimated to have reduced life expectancy by about 1.7 years in the United States and globally. Addressing global health requires an understanding of the leading causes of death and disability so resources can be targeted where they can be most effective.

LIFE EXPECTANCY

Life expectancy is highly variable across the globe (Fig. 5-1), ranging from 51.8 years in Lesotho to 84.8 years in Singapore.[1] Life expectancy in Africa is markedly lower than in other parts of the world. Even within a single country, however, major disparities may exist. In the United States, for example, overall life expectancy was 78.9 years in 2019, but it ranged from 74.9 years in West Virginia to 81.7 years in Hawaii. For all racial and ethnic groups, U.S. life expectancy in 2019 ranged from 64.5 years to 91.7 years.

LEADING CAUSES OF DEATHS

Cardiovascular disease and cancers have remained the leading causes of death worldwide across the last three decades (Fig. 5-2). Compared with 1990, noncommunicable disease are more prominent and infectious diseases less prominent among leading causes of death. In general, as the sociodemographic index improves over time, the burden of noncommunicable disease increases. However, such global trends mask disparities at the country level where some countries are still dealing with a heavy infectious disease burden even as they witness a rise in noncommunicable diseases.

The leading causes of death globally vary by age of death (Fig. 5-3). Before the COVID-19 pandemic, infectious diseases were responsible for more deaths in younger age groups globally, with a greater burden of noncommunicable disease in older ages. Diarrheal and lower respiratory infections are more common in younger ages, injuries and self-harm are highest in young adults, and cardiovascular disease and cancer are the main causes of death in the older age groups. The recent declines in malnutrition deaths in some countries is attributed to improved diet, water sanitation, and access to medical care. Despite this progress, however, malnutrition is still the leading cause of burden for some countries. The COVID-19 pandemic reduced life expectancy by about 1.7 years in the U.S.[2] and by about 2.3 years worldwide.

LEADING CAUSES OF DISABILITIES

Over the past three decades, cardiovascular disease has remained the leading cause of disability worldwide (as measured by lost disability-adjusted life years [DALYs], Fig. 5-4).[3] The disability burden from cancer has risen from fourth to second, primarily as a result of longer life expectancy, whereas maternal

and neonatal diseases remained the third leading cause of lost DALYs. The burden of respiratory infections and tuberculosis has declined globally but it remains a major burden in many countries. In low-income countries, for example, respiratory infections were the second leading cause of lost DALYs.

The main contributors to increasing health loss worldwide over the past 30 years, as measured by the largest absolute increase in number of DALYs, includes six causes that largely affect older adults—ischemic heart disease (with the number of related lost DALYs increasing by 50% from 1990 to 2019), diabetes (up almost 150%), stroke (up over 30%), chronic kidney disease (up over 90%), lung cancer (up almost 70%), and age-related hearing loss (up over 80%) Additionally, four causes of disability that are common from teenage years into old age have also increased: human immunodeficiency virus (HIV; up about 130% over the past 3 decades), musculoskeletal disorders (also up about 130%), low back pain (up nearly 50%), and depressive disorders (up about 60%).

The age-standardized loss of DALYs varies substantially across the globe (Fig. 5-5).[4] In general, the burden is much higher in Africa, particularly the Central African Republic and Lesotho, compared with the remainder of the world. The burden is also high in Afghanistan. The global obesity epidemic partly explains why the number of DALYs due to ischemic heart disease rose by more than 400% in the Philippines from 1990 to 2019, and the number of lost DALYs due to diabetes rose by more than 1000% in the United Arab Emirates. In Singapore, Iceland, Norway, Ireland, Australia, New Zealand, and Qatar, more than half of all lost DALYs is now due to disability caused by noncommunicable diseases and injuries. Ethiopia, Sudan, and Bangladesh have seen 2% or greater annual reductions in age-standardized DALY rates.

LEADING UNDERLYING RISK FACTORS

Changes in mortality and morbidity reflect a variety of underlying causes.[5] Among the leading age-standardized risk factors that lead to loss of DALYs for all ages and both sexes, child and maternal malnutrition remain most prominent (Fig. 5-6). An important trend is the rise of risk factors for noncommunicable diseases, such as high systolic blood pressure, elevated fasting plasma glucose levels, and high body mass index. These risk factors vary tremendously by the sociodemographic index of countries. In countries with a low sociodemographic index, the leading risk factors for loss of DALYs are child and maternal malnutrition, air pollution, unsafe water, poor sanitation, and lack of hand-washing. By comparison, the leading risk factors in countries with high sociodemographic indexes are tobacco, high body mass index, and high fasting plasma glucose levels.

CHANGING PATTERNS OF DISEASE

Although morbidity and mortality from malnutrition and communicable diseases have declined markedly worldwide, especially in children, parts of Africa, Asia, and Latin America face not only a continued burden of persistent infectious diseases (e.g., HIV, malaria, tuberculosis, and other bacterial infections[6]) but also a rise in noncommunicable diseases (e.g., obesity, diabetes, hypertension). As the world's population ages, more and more people worldwide are now living with chronic health conditions. As a result, noncommunicable diseases, such as cardiovascular disease and diabetes, now account for nearly two-thirds of the global burden of disease, even in low- and middle-income countries.

In developing countries, malnutrition, especially in poorer and more rural areas, coexists with obesity, primarily in urban and more affluent segments of the population.[7] Rising rates of obesity (Chapter 201), diabetes (Chapter 210), smoking (Chapter 363), and often-undiagnosed hypertension (Chapter 64) in low-income countries portend a major future increase in cardiovascular diseases.[8]

THE GLOBAL HEALTH CHALLENGE

Many deaths that occur globally could have been prevented with access to high-quality health care. The Health Access and Quality of Care Index, which is

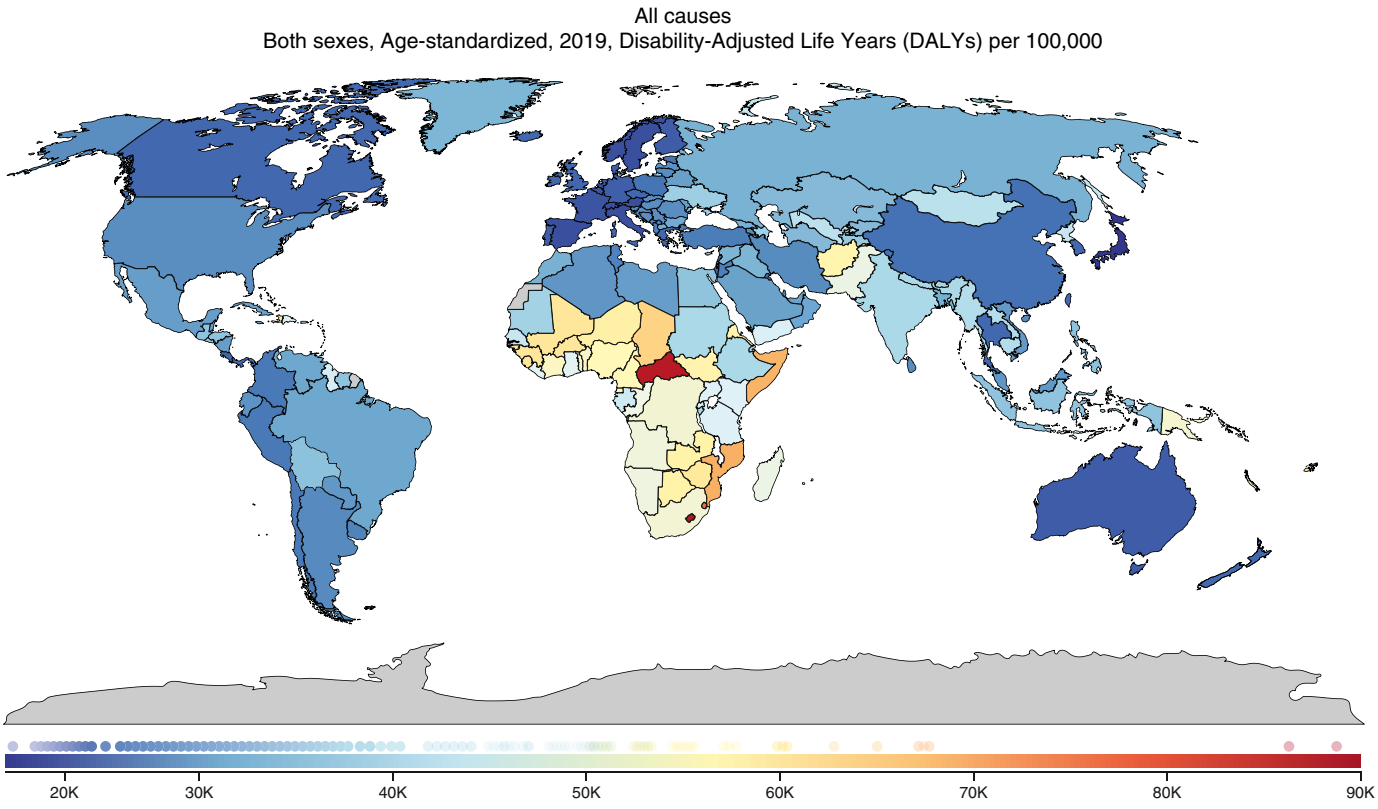

FIGURE 5-5. Age-standardized loss of disability-adjusted life years globally. (Available from Global Burden of Disease 2019, Institute for Health Metrics and Evaluation. https://www.healthdata.org/data-visualization/gbd-compare. Accessed November 16, 2022.)

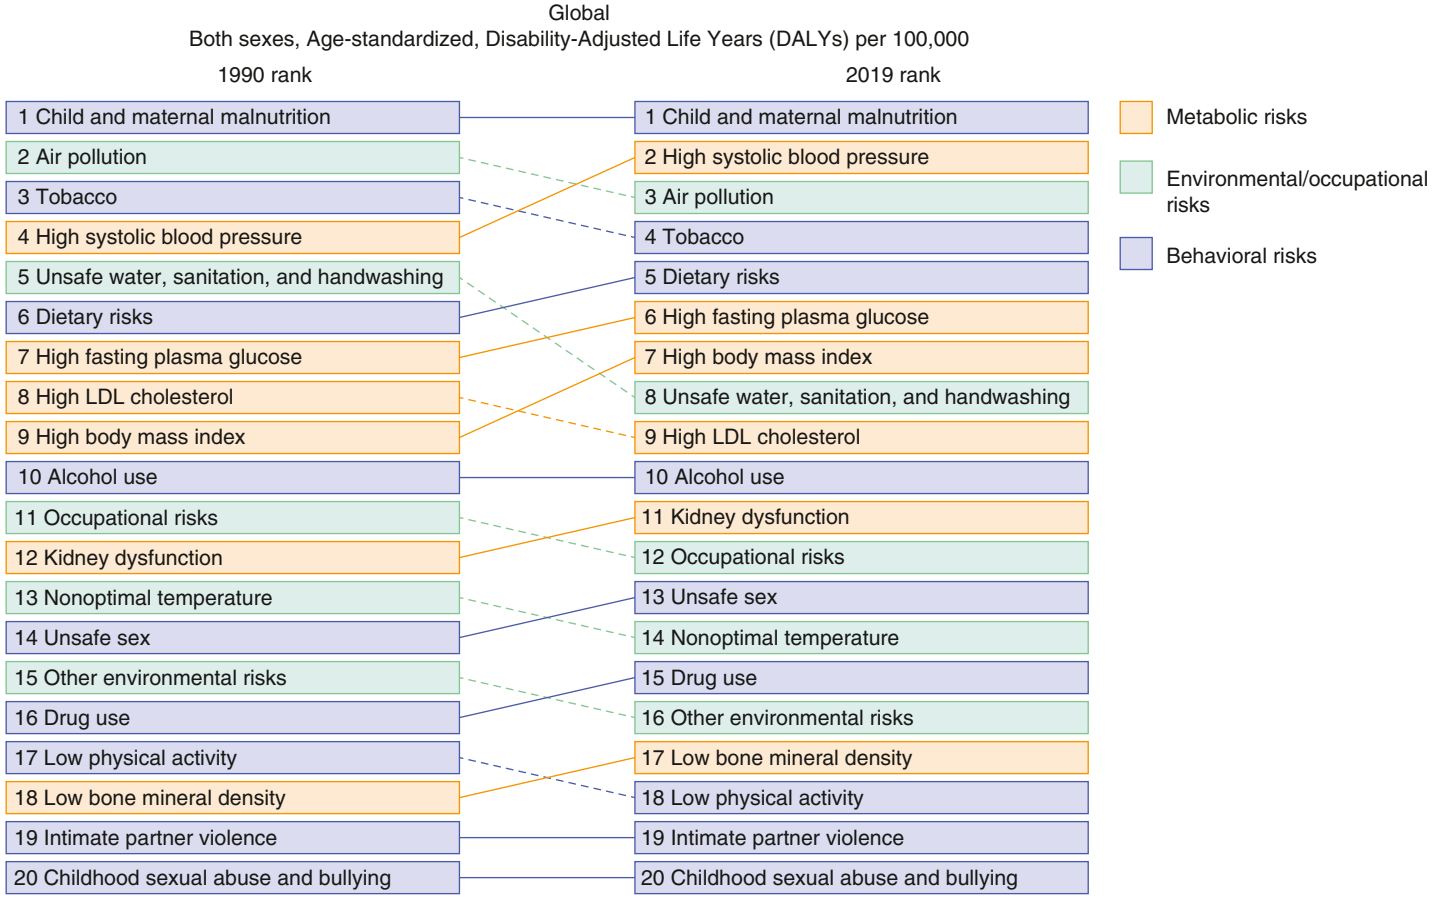

FIGURE 5-6. Age-standardized leading risk factors for loss of disability-adjusted life years globally. LDL = low-density lipoprotein. (Available from Global Burden of Disease 2019, Institute for Health Metrics and Evaluation. https://www.healthdata.org/data-visualization/gbd-compare. Accessed November 16, 2022.)

based on 32 causes of deaths that should not occur in the presence of effective health care,[9,10] range from a high of 97.1 (with 100 as the highest index of access and quality of care) in Iceland to a low of 18.6 in the Central African Republic. Second, health is strongly linked to economic development. Countries that made greater improvements in the human capital index (calculated as the number of years a person can be expected to work in the years of peak productivity, considering life expectancy, functional health, years of schooling, and learning)[11] had faster per capita economic growth. These findings highlight the need for countries to invest in health and education so as to improve their economies by improving the productivity of their labor forces.[12] Only by understanding the current health spending landscape can decision makers better allocate resources, technology, and innovation to improve health outcomes.

The COVID-19 pandemic has exacerbated already deep health disparities and demonstrated the weaknesses in worldwide public health systems. Vaccines and life-saving interventions have not been available in many parts of the world. Even in resource-rich countries, vaccination rates have often been disappointing. Excess global mortality from COVID-19 was about 17 million by the end of 2021,[13] with a huge impact on mental health[14] and gender equity.[15] Much of the recent gains in life expectancy have been reversed, with life expectancy falling to below what it was in 2013.

Global health efforts aimed to reduce infectious diseases and improve prenatal care have markedly improved the health of children under 10 years of age worldwide in the past few decades, with the overall burden of disease declining by approximately 55%. Unfortunately, this progress has not been matched in other age groups. For example, despite increased recognition of the importance of adolescent health to global development and future economic prosperity, the world failed to respond to health risks during adolescence and young adulthood (ages 10 to 24 years).[16]

Addressing social determinants of health could bring substantial health and economic benefits. Programs to improve diet quality (Chapter 13), increase physical activity (Chapter 14), and promote smoking cessation (Chapter 363) can yield large health benefits. Unfortunately, many low- and middle-income countries spend far less than 5% of their comparatively low gross domestic product on health care and, as a result, cannot address their domestic health needs.

As shown by the COVID-19 pandemic, infectious disease, like climate (Chapter 17), are worldwide issues regardless of the country or countries that may be initially or most responsible. The COVID-19 pandemic has demonstrated the importance of a strong public health infrastructure, as well as modern acute health care capabilities. However, global health threats will require not only country-specific resources and infrastructures but also general cooperation and responses. Affluent countries, which have provided poorer countries with low-cost or free treatments for HIV and onchocerciasis (Chapter 327), now must be encouraged to help countries with limited resources improve access to health care and public health programs. The sharing of expertise can also ensure that countries allocate resources to effective programs and wisely use limited resources.

6 HISTORY AND PHYSICAL EXAMINATION

DAVID L. SIMEL

OVERVIEW

Physicians may have multiple objectives with varying degrees of importance in their encounters with patients. These goals include, but are not limited to, the translation of symptoms and signs into diagnoses, the assessment of stability or change in known conditions, the provision of information and counseling for future prevention, and the reaffirmation or alteration of therapeutic interventions. For a healthy adult with no symptoms or signs of a problem, age-specific and risk-specific screening guidelines should be followed (Chapter 12), but a comprehensive annual physical examination is not recommended.

The interaction between the patient and physician represents not only a scientific encounter but also a social ritual centered on the locus of control of patient and physician and meeting each other's expectations. Patients expect a competent assessment of their health care needs and concerns. Physicians need to feel that they have not missed something important, an occasional need to put limits on the time available for each interaction, and a need to maintain objectivity. The expertly performed rational clinical examination enhances the social ritual and the likelihood of acquiring relevant data. It also optimizes the physician's ability to understand the patient's symptoms and concerns, as well as to facilitate the healing process. The comprehensiveness of a clinical evaluation depends on the time available, whether the episode of care was prompted by specific concerns, whether the evaluation is an intake evaluation to establish a long-term relationship with the patient, or whether the setting is in acute care. The coronavirus disease 2019 (COVID-19) pandemic rapidly advanced the use of telemedicine by clinicians who were forced to learn new creative methods for the physical examination.

MEDICAL HISTORY

The history begins by asking patients to describe, in their own words, the reason for seeking medical care (Table 6-1). Although patients may have many reasons for initiating a visit to the physician, they should be encouraged to select the one or two most important concerns they have. Physicians should reassure patients with multiple worries that other concerns will not be ignored, but emphasize that it is important to understand what worries them most.

HISTORY OF THE PRESENT ILLNESS

Open-ended questions facilitate descriptions of problems in the patient's own words. Subsequently, specific questions fill in gaps and help clarify important points. However, wise clinicians realize that when they are talking, they are not listening. Nonetheless, when the patient is acutely ill, the physician should limit the amount of time spent in open-ended discussion and move promptly to the most important features that allow quick evaluation and management. In general, the history of the problem under consideration includes the following:

- Description of onset and chronology
- Location of symptoms
- Character (quality) of symptoms
- Intensity
- Precipitating, aggravating, and relieving factors
- Inquiry into whether the problem or similar problems occurred before and, if so, whether a diagnosis was established

It is often helpful to ask patients to express what they believe is the cause of the problem or what concerns them the most. This approach often uncovers other pertinent factors and helps establish that the physician is trying to meet the patient's needs.

PAST MEDICAL AND SURGICAL HISTORY

An astute clinician recognizes that patients may not report all their prior problems because they may forget, may assume that previous events are unrelated to their current problem, or simply may not want to discuss past events. Open-ended statements such as "Tell me about other medical illnesses that we did not discuss" and "Tell me about any operations you had" prompt the patient to consider other items. The physician should ask the patient about unexplained surgical or traumatic scars.

A list of current medications includes prescriptions, over-the-counter medications, vitamins, and herbal preparations. Patients who do not recall the names of medications should bring all medication bottles to the next visit. Patients may not consider topical medications (e.g., skin preparations or eye-drops) as important, so they may need prompting.

Information about allergies (Chapter 234) is particularly important, but challenging, to collect. Patients may attribute adverse reactions or intolerances to allergies, but many supposed allergic reactions are not truly drug allergies. Eliciting the patient's actual response to medications facilitates a determination of whether the response was a true allergic reaction.

SOCIAL AND OCCUPATIONAL HISTORY AND RISK FACTORS

The social history not only reveals important information but also improves understanding of the patient's unique values, support systems, and social situation. It can be helpful to ask the patient to describe what they would do during a recent typical day when they were well, and more recently if they have been affected by changes in their health or social situation. Physicians must consider whether inherent bias, especially about race, gender, and gender identity, affects their assessment of the patient.

Data that may influence risk factors for disease should be gathered, including a nonjudgmental assessment of substance abuse (Chapter 365). The tobacco history should include the use of snuff, chewing tobacco, cigar and cigarette smoking, and electronic nicotine delivery systems (Chapter 363). Alcohol use should be determined quantitatively and by the effect that it has had on the patient's life (Chapter 364). Past or present use of prescription pain medications, sedatives, or illicit substances should be assessed (Chapter 365). The sexual history should address sexual orientation and gender identity, as well as current and past sexual activity. The best way to address sexual orientation and gender identity may be to ask the patient whether they think of themselves as "lesbian, gay, or homosexual; as straight or homosexual; as bisexual; as something else; or whether they 'don't know.'"[1] The employment history should include the current and past employment history, as well as any significant hobbies. All adult patients should be asked if they served in the military. Military veterans should be asked about their combat history, years of service, and areas of deployment.[2] In patients in whom exposure to trauma has been established, screening for post-traumatic stress disorder (PTSD; Chapter 362) can be done with several simple questions (Table 6-2). Post-traumatic stress disorder is not just a consequence of military service, so all patients should be screened for prior traumatic events and their current response to them.

The physician should obtain information on socioeconomic status, insurance, the ability to afford or obtain medications, and past or current barriers to health care (Chapter 4). Marital status and the living situation (i.e., whom the patient lives with, significant stressors for that patient) are important as risk factors for disease and to determine how best to care for the patient. A patient's culture (Chapter 4) and values should be known, including any prior advance directives or desire to overrule them (Chapter 3).

FAMILY HISTORY

The family history allows risk stratification, which affects the pretest probability for an increasing number of disorders.[3] For common diseases such as heart disease, additional inquiry into the age of onset in first-degree relatives and death attributed to the disease should be obtained (Chapter 40). Patients may lack appropriate information about the absence of disease.

REVIEW OF SYSTEMS

The review of systems elicits symptoms or signs not covered or overlooked in the history of the present illness, though no evidence suggests that a complete review of symptoms is necessary at each patient evaluation (Table 6-3).[4] The review of systems is more efficient when the questions are restricted to a specific period (e.g., "a recent change in your vision" or "shortness of breath, wheezing, or coughing this past week") or by having the patient fill out a previsit questionnaire.

PHYSICAL EXAMINATION

CHAPERONES

When a guest or friend accompanies the patient, the clinician should either ask the patient if they would like their companion to stay during the examination or ask the guest to wait outside the room. Patients can be offered the option of a chaperone, especially when the clinician and patient are of different genders and a comprehensive examination is planned. Many examiners prefer a chaperone to allay their own anxieties attributable to gender differences or to

ABSTRACT

The clinical examination provides data that are part of a scientific inquiry and is also an important social ritual that establishes and maintains a relationship between the physician and patient. As part of a scientific inquiry, the physician should focus on symptoms and signs that are of proven value, while at the same time demonstrating professionalism and caring that respects a patient's preferences and goals.

KEYWORDS

medical history
symptoms
physical examination

TABLE 6-1 PATIENT'S MEDICAL HISTORY

Description of the patient
Age, sexual orientation and gender identity, racial and ethnic background, language, occupation
Chief reason for seeking medical care
State the purpose of the evaluation (usually in the patient's words)
Other physicians involved in the patient's care
Include the clinician that the patient identifies as his or her primary provider or the physician who referred the patient. Record contact information for all physicians who should receive information about the visit
History of the reason for seeking medical care
In chronologic fashion, determine the evolution of the indication for the visit and then each major symptom. It is best to address the patient's reason for seeking care first rather than what the physician ultimately believes is most important
Be careful to avoid "premature closure," when a diagnosis is assumed before all the information is collected
Past medical and surgical history
List other illnesses and previous surgeries not related to the current problem
List all prescribed and over-the-counter medications with dose; remember to ask about vitamin and herbal supplements
Allergies and adverse reactions
List allergic reactions to medications and food. Record the specific reaction (e.g., hives). Distinguish allergies from adverse reactions or intolerance to medication (e.g., dyspepsia from nonsteroidal anti-inflammatory agents)
Social, occupational, and military history (see Table 6-2)
Describe the patient's current family and a typical day for patient
Risk factors/habits
Physical activity
Use of tobacco, alcohol, and drugs
Risk factors for sexually transmitted disease (including human immunodeficiency virus and hepatitis)
Family history
History of any diseases in first-degree relatives and a listing of family members with any conditions that could be risk factors for the patient (e.g., cardiovascular disease at a young age, malignancy, known genetic disorders, longevity)
Review of systems (see Table 6-3)

TABLE 6-2 HISTORY OF MILITARY SERVICE AND POST-TRAUMATIC STRESS

- Tell me about your military experience.
- When and where do you/did you serve?
- What do you/did you do while in the service?
- How has military service affected you?

If the patient answers "yes" to any of the questions below, ask the patient, "Can you tell me more about that?"

- Did you see combat, enemy fire, or casualties?
- Were you or a buddy wounded, injured, or hospitalized?
- Did you ever become ill while you were in the service?
- Were you a prisoner of war?

To screen for post-traumatic stress disorder, ask, "In your life, have you ever had an experience so horrible, frightening, or upsetting that, in the past month you…"

- Have had nightmares about it or thought about it when you did not want to?
- Tried hard not to think about it or went out of your way to avoid situations that reminded you of it?
- Were constantly on guard, watchful, or easily startled?
- Felt numb or detached from others, activities, or your surroundings?

TABLE 6-3 REVIEW OF SYSTEMS*

FOCUS all questions on a specific time frame (e.g., within the past "month" or "now") and on items not already addressed during the clinical examination:
Change in weight or appetite
Change in vision
Change in hearing
New or changing skin lesions
Chest discomfort or sensation of skipped beats
Shortness of breath, dyspnea on exertion
Abdominal discomfort, constipation, melena, hematochezia, diarrhea
Difficulty with urination
Change in menses
Joint or muscle discomfort not already mentioned
Problems with sleep
Difficulty with sexual function
Exposure to "street" drugs or medications not already mentioned
Depression (feeling "down, depressed, or hopeless"; loss of interest or pleasure in doing things)
A sensation of unsteadiness when walking, standing, or getting up from a chair

*Start with this basic list and adapt the items by considering factors such as age, gender, medications, and the problems identified during the examination. The process is facilitated by developing a routine personal approach to these questions, typically going through the systems from "head to toe."

achieve a perceived need for protection should the patient become concerned during the procedure.

VITAL SIGNS

Vital signs include the pulse rate and rhythm, blood pressure, respiratory rate, and body temperature. Marked abnormalities require a rapid, focused evaluation that may take precedence over the typical structural approach to the remainder of the evaluation (Chapter 7).

When the blood pressure is abnormal (Chapter 64), the measurement should be repeated, assuring that the cuff size is appropriate. Because of inherent variability in blood pressure, and the prevalence of both white coat hypertension on the one hand and masked hypertension on the other, the clinician is now advised to confirm hypertension through review of measurements obtained outside of the clinical setting.[5]

Respirations should be assessed with the patient unaware that the rate is being observed. Abnormal patterns include tachypnea (rapid rate of breathing) or hypopnea (slow or shallow rate of breathing). Tachypnea is not always associated with hyperventilation, which is defined by increased alveolar ventilation resulting in a lower arterial carbon dioxide level (Chapter 89). Dyspnea is a subjective sensation claimed by the patient,[6] and patients with hypoxemia do not always complain of breathlessness. The clinician should listen for whether the patient can complete sentences without taking a breath and should observe them for increased work of breathing.

The body temperature of adults is measured with an oral electric thermometer. Tympanic thermometers vary too much in comparison with oral thermometers (−1.2° to +1.6° C vs. the oral temperature) to be reliable in hospitalized patients, but they can be useful when continuous monitoring is important.

HEAD AND NECK

Face

The examiner should note any asymmetrical facial features. Examples of asymmetry include skin lesions (Chapter 403), cranial nerve palsies (Chapter 366), parotid enlargement (Chapter 393), or the ptosis of Horner syndrome (Chapter 392). A variety of disorders may cause symmetrical, abnormal facies; examples include acromegaly (Chapter 205), Cushing syndrome (Chapter 208), and Parkinson disease (Chapter 378).

Ears

Physicians may not recognize their patient's hearing impairment (Chapter 396) unless they perform a whispered voice test. Otoscopic evaluation of the tympanic membranes should reveal a translucent membrane with an obvious cone of light reflected where the eardrum meets the malleolus (see Fig. 394-12 in Chapter 394). Cerumen impaction is an easily treated cause of diminished hearing.

Nose

Patients with nasal symptoms often incorrectly self-diagnose bacterial sinusitis (Chapter 394). The physician should inspect the nares for polyps that are obstructing, glistening, mucosal masses. Transillumination performed in a dark room is useful for diagnosing sinusitis, especially when combined with visualization of a purulent discharge, a patient's report of a poor response to decongestants or antihistamines, maxillary toothache, and the presence of discolored rhinorrhea (Chapter 394).

Mouth

The quality of the patient's dentition directly affects nutrition. Premalignant oral lesions (e.g., leukoplakia [see Fig. 393-3 in Chapter 393], nodules, ulcerations) found by generalist physicians are usually verified by dentists (Chapter 393). Patients who use smokeless tobacco products are at significantly increased risk for premalignant and malignant oral lesions (Chapter 363). Bimanual palpation of the cheeks and floor of the mouth facilitates identification of potentially malignant lesions (Chapter 393).

Eyes

The eye examination begins with simple visual inspection to look for symmetry in the lids, extraocular movements, pupil size and reaction, and the presence of redness (Chapters 391 and 392). Abnormal extraocular movements should be grouped into nonparalytic (usually chronic with onset in childhood) or paralytic causes (third, fourth, or sixth cranial nerve palsy). Pupillary abnormalities may be symmetrical or asymmetrical (anisocoria). Red eyes should be categorized by the pattern of ciliary injection, presence of pain, effect on vision, and papillary abnormalities. When the eye examination is approached systematically, the generalist physician can evaluate red eyes for conjunctivitis, episcleritis or scleritis, iritis, and acute glaucoma.

Routine determination of visual acuity can confirm a patient's report of diminished vision but does not replace the need for formal ophthalmologic evaluation in patients with visual complaints (Chapter 391). Novice examiners will find ophthalmoscopes with panoptic views easier to use than the direct ophthalmoscope, resulting in better sensitivity and specificity for optic disc abnormalities. After identifying the optic disc by ophthalmoscopy, the examiner should note the border of the disc for clarity, color, and the size of the central cup in relation to the total diameter (usually less than half the diameter of the disc). A careful observer usually can see spontaneous venous pulsations that indicate normal intracranial pressure, but about 10% of patients with normal intracranial pressure will not have spontaneous pulsations. Abnormalities of the optic disc include optic atrophy (a white disc), papilledema (see Fig. 391-25 in Chapter 391) (blurry margins with a pink, hyperemic disc), and glaucoma (a large, pale cup with retinal vessels that dive underneath and that may be displaced toward the nasal side). The generalist's examination inadequately detects early glaucomatous changes, so high-risk patients should undergo routine ophthalmologic examination for glaucoma.

After inspecting the disc, the upper and lower nasal quadrants should be examined for the appearance of vessels and the presence of any retinal hemorrhages (see Fig. 391-22 in Chapter 391) or lesions. Patients with diabetes (Chapter 210) should undergo routine examination by eye care experts because the sensitivity of a generalist's examination is not adequate to exclude diabetic retinopathy or monitor it over time.

Neck

Carotid Pulses

The carotid pulses should be palpated for contour and timing in relation to the cardiac impulse. Abnormalities in the carotid pulse contour reflect underlying cardiac abnormalities (e.g., aortic stenosis) but are generally appreciated only after detecting an abnormal cardiac impulse or murmur (Chapter 39). Many physicians listen for bruits over the carotid arteries because asymptomatic carotid bruits are associated with an increased incidence of cerebrovascular and cardiac events in older patients (Chapters 375 and 376). Unfortunately, clinical studies do not provide adequate data for judging the importance of detecting bruits in asymptomatic patients.

Jugular Veins

Inspection of the venous waveforms may facilitate the interpretation of the cardiac examination for right heart valvular lesions. The waveforms can be highlighted by shining a penlight obliquely on the vein while looking for the dynamic changes of the projected shadow on the bed linen. The examination of the neck veins is an unreliable indicator of central venous pressure or fluid responsiveness in hemodynamically unstable patients (Chapter 39). Increased respiratory collapse of the inferior vena cava seen with bedside ultrasound or increased cardiac output during passive leg raising are better examination predictors for fluid responsiveness.

Thyroid

About 4 to 7% of the general asymptomatic population will have thyroid nodules detected on physical examinations.[7] The thyroid gland is felt best when standing behind the patient and using both hands to palpate the thyroid gland gently (Chapter 207). Palpation is enhanced when the patient swallows sips of water to allow the thyroid to glide underneath the fingers. When viewed from the side, lateral prominence of the thyroid between the cricoid cartilage and the suprasternal notch indicates thyromegaly. The volume of a normal thyroid gland is no greater than the volume of the patient's distal thumb phalanx.

Lymphatic System

While palpating the thyroid, the examiner may also identify enlarged cervical lymph nodes (Chapter 154). Lymph nodes can also be palpated in the supraclavicular area, axilla, epitrochlear area, and inguinofemoral region. Simple lymph node enlargement confined to one region is common and does not usually represent an important underlying disorder. Unexpected gross lymph node enlargement in a single area or diffuse lymph node enlargement is more important. Patients with febrile illnesses, underlying malignancy, or inflammatory diseases should routinely undergo an examination of each of the aforementioned areas for lymph node enlargement.

CHEST

Inspection of the patient's posture may reveal lateral curves in the back (scoliosis) or kyphosis that may be associated with loss of vertebral height from osteoporosis (Chapter 225). When patients have back pain, the spine and paravertebral muscles should be palpated for spasm and tenderness (Chapter 369). The patient may be placed through maneuvers to assess loss of mobility associated with ankylosing spondylitis (Chapter 244), but a history of loss of lateral mobility may be just as efficient in the early stages of spondylitis.

LUNGS

The incremental value of palpation and percussion of the chest to supplement the history, auscultation, and eventual chest radiograph is unknown. Normal vesicular sounds, which approximate a 3 : 1 inspiratory : expiratory ratio with no pause between inspiration and expiration, are heard throughout most of the normal posterior chest during quiet breathing. Auscultated wheezes are continuous adventitial sounds. Crackles (formerly called rales) are discontinuous sounds heard in conditions that stiffen the lung (heart failure, pulmonary fibrosis, and obstructive lung disease[8]).

HEART

The heart examination is an important prelude to the possible ordering of further cardiac diagnostic tests.[9] The patient should be examined in the sitting and lying positions (Chapter 39). Palpation of the apical impulse in the left lateral decubitus position helps detect a displaced apical impulse and can reveal a palpable S_3 gallop. When the apical impulse is lateral to the midclavicular line, radiographic cardiomegaly and an ejection fraction of less than 50% are more likely. Most examiners auscultate in sequence the second left and right intercostal spaces, the left sternal border, and then the apex. The examiner should concentrate on the timing, intensity, and splitting of sounds with respiration. The first and second heart sounds are heard best with the diaphragm, as are pericardial rubs. Gallops (S_3 and S_4) are heard best with the stethoscope bell. High-pitched sounds are easier to hear with the diaphragm and low-pitched sounds easier to hear with the bell, while medium-pitched sounds are heard equally well with either. The location, timing, intensity, radiation patterns, and respiratory variation of murmurs should be noted. Special maneuvers during auscultation (e.g., Valsalva, auscultation during sudden squatting or standing) do not need to be performed if the results of routine precordial examination are entirely normal.

The presence of an S_3 gallop is useful for detecting left ventricular systolic dysfunction. The presence of a systolic thrill or a holosystolic murmur increases the likelihood of moderate to severe aortic stenosis or mitral regurgitation. Quiet systolic murmurs are unlikely to herald important cardiac abnormalities. A loud, early diastolic murmur or a diastolic murmur associated with an S_3 suggests severe aortic regurgitation.

BREAST

Physical breast examination by physicians is no longer recommended as a routine screening test among women at average risk. However, women may present with concerns identified through their self-examinations. The most important determinants of the accuracy of the breast examination are the duration of the examination; the patient's position; careful evaluation of the breast boundaries; the pattern of the examination; and the position, movement, and pressure of the examiner's fingers (Chapter 183). To obtain the best sensitivity, the duration of the breast examination needs to be 5 to 10 minutes' total time, but few generalist physicians perform such a lengthy examination. Clinicians should recognize that the examination may make them (or their patient) feel uncomfortable—the presence of a chaperone may give the clinician the confidence to perform an intensive examination.

The physician should palpate the breast with the pads of the fingers while the patient is supine and holding her hand first on her forehead (to flatten the lateral border of the breast) and then on her shoulder (to flatten the medial border). The examiner should make small circular motions with the fingers, moving up and down in parallel rows to span the entire breast-clavicle to the bra line. Cancerous breast lumps are difficult to distinguish from benign breast lumps, which is why breast imaging now dominates recommendations for screening and follow-up of clinical abnormalities.

ABDOMEN

When patients have an acute abdominal problem, the examination focuses initially on identifying patients who require surgical evaluation. Palpation and percussion of the abdomen of patients with no symptoms or risk factors for an abdominal disorder seldom reveal important abnormalities (Chapter 118). Palpation can reveal an asymptomatic widening of the abdominal aorta that, in older patients, suggests an abdominal aneurysm. However, palpation misses a substantial proportion of small to medium aneurysms (Chapter 63).

The presence of bowel sounds in patients with acute symptoms can be falsely reassuring because the sounds may increase early in an obstruction and then persist despite an ileus. For patients without gastrointestinal symptoms or abnormalities on palpation, auscultation for bruits is important primarily to detect renal bruits in patients with hypertension (Chapters 64 and 110). The presence of an abdominal bruit in a hypertensive patient, if heard in systole and diastole, strongly suggests renovascular hypertension.

LIVER

Detection of liver disease depends mostly on the history and laboratory evaluations (Chapter 132). By the time that signs are present on physical examination, the patient usually has advanced liver disease. The first abnormalities on physical examination associated with liver disease may be extrahepatic. The clinician should assess the patient for ascites, peripheral edema, jaundice, or splenomegaly. In patients with an enlarged liver, palpation should begin at the liver edge, but palpation of the edge below the costal margin increases the likelihood of hepatomegaly only slightly. Percussion may detect the upper border of the liver, and a span of less than 12 cm reduces the likelihood of hepatomegaly.

SPLEEN

Examination for splenomegaly in patients without findings suggestive of a disorder associated with splenomegaly almost always reveals nothing (Chapter 154). Approximately 3% of healthy teenagers may have a palpable spleen. The examination for an enlarged spleen begins first with percussion in the left upper quadrant to detect dullness. Palpation can be performed by palpating with the right hand while providing counterpressure with the left hand behind the spleen. Alternatively, the examiner can palpate with one hand without counterpressure while the patient is in the right lateral decubitus position. With the patient supine while the examiner stands cephalad to the spleen, the fingers can be hooked lightly under the left lower rib cage to feel the spleen as the patient takes a deep breath.

MUSCULOSKELETAL SYSTEM

The patient's symptoms direct the musculoskeletal examination (Chapters 236 and 242). Most patients have back pain at some point during their life (Chapter 369). The patient's history helps assess the likelihood of an underlying systemic disease (age, history of systemic malignancy, unexplained weight loss, duration of pain, responsiveness to previous therapy, intravenous drug use, urinary infection, or fever). The most important physical examination findings for lumbar disc herniation in patients with sciatica are ipsilateral straight leg raising causing pain, contralateral straight leg raising causing pain, and ankle or great toe dorsiflexion weakness. Evaluation of hip motion and pain during motion helps detect hip osteoarthritis.[10]

The generalist physician should evaluate an adult patient with knee discomfort for torn menisci or ligaments. A variety of maneuvers assess for pain, popping, or grinding along the joint line between the femur and tibia to evaluate for meniscal tears. A tear in the ligaments eliminates a discrete endpoint when the anterior, medial, or posterior ligaments are stressed. As with many musculoskeletal disorders, no single finding has the accuracy of the orthopedist's examination, which factors in the history and a variety of clinical findings.

The shoulder examination[11] is directed toward determining range of motion, maneuvers that cause discomfort, and assessment of functional disability. Hip osteoarthritis is detected by evidence of restriction of internal rotation and abduction of the affected hip. The degree of pain and disability experienced by the patient may prompt confirmation of the diagnosis and referral.

The hands and feet[12] may show evidence of osteoarthritis (local or as part of a systemic process) (Chapter 241), rheumatoid arthritis (Chapter 243), gout (Chapter 252), or other connective tissue diseases. In addition to regional musculoskeletal disorders, such as carpal tunnel syndrome, a variety of medical and neurologic conditions should prompt routine examination of the distal ends of the extremities to prevent complications (e.g., diabetes [neuropathy or ulcers] or hereditary sensorimotor neuropathy [claw toe deformity]).

SKIN

The skin should be examined under good lighting (Chapter 403). It is best to ask the patient to point out any spots on the skin of concern. Examiner agreement on some of the most important features of melanoma (asymmetry, haphazard color, border irregularity) is fair to moderate (Chapter 188). A lesion that is symmetrical, has regular borders, is only one color, is 6 mm or smaller, or has not enlarged in size is unlikely to represent a melanoma. However, an increasing number of these findings greatly enhance the likelihood of melanoma (Chapter 188).

Basal cell carcinoma and squamous cell carcinoma occur more frequently than melanoma (Chapter 188). The examiner should pay particular attention to sun-exposed areas of the nose, face, forearms, and hands.

NEUROLOGIC EXAMINATION

Full details of the neurologic examination are given in Chapter 366.

PSYCHIATRIC EVALUATION

During the general examination, much of the psychiatric assessment (including cognition) is accomplished while eliciting the routine history and performing the review of systems (Chapter 362). Observation of the patient's mannerisms, affect, facial expression, thought content, and behavior may suggest underlying psychiatric disturbances. Specific questioning for symptoms of depression (Table 362-3) is appropriate for all adult patients. Delirium (Chapter 361) is common in both medical and surgical inpatients and is recognized by fluctuating mental status. Suspect delirium when the patient has trouble carrying on a normal conversation during bedside rounds. The patient's nurse or visitors may detect delirium before the physician.

PELVIC EXAMINATION

A complete examination includes a description of the external genitalia, appearance of the vagina and cervix as seen through a speculum, and bimanual palpation of the uterus and ovaries (Chapters 184 and 219). However, current evidence is insufficient to assess whether an annual screening pelvic examination is necessary in the asymptomatic and not pregnant adult woman. In the emergency setting, all women of reproductive age with vaginal bleeding and pelvic pain should have a pregnancy test and an ultrasound to evaluate for a possible ectopic pregnancy. The diagnosis of transgender and gender incongruence should be made by clinicians with expertise in the diagnostic criteria. Likewise, the ongoing care of transgender and gender-incongruent patients is best delivered by clinicians with experience in this field (Chapter 215).[13]

MALE GENITALIA

Examination of the male genitalia should begin with a description of whether the penis is circumcised and whether there are any visible skin lesions (e.g., ulcers or warts). Palpation should confirm the presence of bilateral testes in the scrotum. The epididymis and testes should be palpated for nodules. The low incidence of testicular carcinoma means that most nodules are benign (Chapter 185).

As a screening test for prostate carcinoma, no evidence supports a digital rectal examination in the absence of an elevated serum prostate-specific antigen.[14] The generalist physician will more frequently perform a digital examination to evaluate for tenderness associated with prostatitis or enlargement causing lower urinary tract symptoms. The size of the prostate can be described by centimeters of width and height.

RECTUM

Patients can be examined while lying on their side, during a gynecologic bimanual exam, or while standing and leaning over a table. The rectal examination begins with inspection of the perianal area for skin lesions. A well-lubricated, gloved finger is placed on the anus, and while applying gentle digital pressure, the examiner asks that the patient bear down as though having a bowel movement. This maneuver facilitates entry of the finger into the rectum. A normal rectal response includes tightening of the anal sphincter around the finger. The examiner should palpate circumferentially around the length of the fully inserted finger for masses. As a screening test for colorectal carcinoma (Chapter 179), digital examination does not replace testing stool samples collected by the patient.

TELEHEALTH

The increase in telehealth visits, especially during the severe acute respiratory syndrome coronavirus 2 pandemic (Chapter 336), has made the physical examination more challenging. With the help of digital devices (for heart rate and electrocardiogram), home monitoring devices (for weight, blood

pressure, and pulse oximetry), and a caregiver (if needed), a focused physical examination can be performed virtually.[15]

SUMMARIZING THE FINDINGS FOR THE PATIENT

The clinician should summarize pertinent positive and negative findings for the patient and be willing to express uncertainty, provided that uncertainty is accompanied by a plan of action (e.g., "I will reexamine you on your next visit"). The rationale for subsequent laboratory, imaging, or other tests should be explained. A plan should be established for providing further feedback and results to the patient, especially when there is a possibility that bad news may need to be delivered. Some physicians ask the patient if there is "anything else" to be covered. Patients who express additional new concerns at the end of the visit may have been fearful to address them earlier; when the problems seem non-urgent, it is acceptable to reassure the patient and offer the promise of evaluating the patient in a follow-up phone call or at the next visit.

FUTURE DIRECTIONS

The common assumption that physicians' diagnostic skills are deteriorating is not supported by evidence. There is considerable evidence that the scientific approach to understanding what is worthwhile and what is not worthwhile during the clinical examination identifies a core set of skills for clinical diagnosticians. These skills have expanded to include bedside ultrasonography,[16] which is of proven benefit in some emergency situations (Chapters 7 and 97). Because good patient outcomes at good value are driven primarily by the quality of the information obtained during the clinical examination, continued application of scientific principles to the history and physical examination should improve diagnostic skills.

APPROACH TO THE PATIENT WITH ABNORMAL VITAL SIGNS

DAVID L. SCHRIGER

Care of the patient is guided by integration of the chief complaint, history, vital signs, and findings on physical examination (Chapter 6). Physicians should be keenly aware of a patient's vital signs, because they are important markers of clinical stability. Although vital signs themselves seldom are the centerpiece of the clinical evaluation, they sometimes become the major focus of urgent care when they themselves pose a life-threatening challenge (Chapters 50, 90, 92, 95).

THE IMPORTANCE OF VITAL SIGNS

The importance of vital signs in medical care is a conundrum for proponents of an evidence-based approach to the care of patients. No experienced physician would be willing to care for patients without them, yet a formal evaluation of the utility of vital signs for making specific diagnoses would conclude that they are not particularly useful because their likelihood ratios are too close to 1 to differentiate patients who have a specific condition from those who do not (Chapter 6). For uncommon conditions, their predictive value is even worse. For example, the probability of tachycardia in a patient in thyroid storm is high, yet the probability of thyroid storm in a patient with isolated tachycardia is low. This application of Bayes theorem (Chapter 8) demonstrates why there is no justification for ordering thyroid tests for every tachycardic patient and why attempts to say "When vital sign *x* is high [low], do *y*" fail. Each vital sign can be normal or abnormal in almost every acute condition (Table 7-1), and vital signs can be transiently abnormal in healthy individuals. An algorithmic approach to testing and treatment in response to abnormal vital signs would be too vague and too complex to be of use.

TABLE 7-1 NORMAL AND PANIC RANGES FOR KEY VITAL SIGNS IN ADULTS*

	NORMAL	PANIC
Temperature	36°-38° C (96.8°-100.4° F)	40° C (104° F)
Pulse	60-100 beats/min	<45 beats/min, >130 beats/min
Respirations	12-20 breaths/min	<10 breaths/min, >26 breaths/min
Oxygen saturation	95-100%	<90%
Systolic blood pressure	90-130 mm Hg	<80 mm Hg, >200 mm Hg
Diastolic blood pressure	60-90 mm Hg	<50 mm Hg, >120 mm Hg

*Normal values are for healthy adults. Values outside these ranges are common in patients who are ill or are anxious about their health care encounter. Panic values demand the health care provider's attention in any adult patient. These values are specific (rarely present in healthy patients at rest) but not sensitive (most ill patients' vital signs will not include panic values). All vital signs must be interpreted in the context of the patient's presentation (see text).

PREDICTIVE VALUE

How can it be that vital signs are poor predictors of diagnoses but central to the practice of medicine? First, although vital signs are insufficiently predictive to be of use in rigid algorithms, these algorithms are but one of several heuristics used by physicians to diagnose and to treat patients. Pattern recognition and the hypothetical-deductive model are heuristics that are based not on average tendencies of a single factor (e.g., hypotension is present in *x*% of cases of septic shock) or a small number of factors (e.g., hypotension and tachycardia are present in *y*% of cases of septic shock) but on the complex interaction of multiple factors (e.g., because this patient is an ill-appearing elderly man with an enlarged prostate and a history of urinary tract infections, is tachycardic and hypotensive, has clear lungs and an enlarged but nontender prostate, and has an oxygen saturation of 97%, he should be treated for urosepsis [Chapter 263] while awaiting results of urinalysis and urine culture). Thus, vital signs can play an important function in medical decision making even though their likelihood ratios for specific conditions are unimpressive.

Despite their poor predictive value for any single diagnosis, abnormal vital signs help identify patients who are sicker.[1] For example, even one abnormal vital sign in the emergency department significantly increases the likelihood of adverse outcomes in elderly patients by about 50%. Abnormal vital signs on emergency department discharge increase the chance of rapid readmission, and abnormal vital signs after admission carry a 20-fold increased risk for subsequent important deterioration. Abnormal vital signs are also a key predictor of which patients are at risk of dying soon after being sent home from an emergency department or after an inpatient admission.[2]

The usefulness of vital signs is also evidenced by the finding that more severe abnormalities are associated with an even worse prognosis. For example, among hospitalized patients, one critically abnormal vital sign carries about a 1% risk for inpatient death, whereas three simultaneously abnormal vital signs carry nearly a 25% risk for inpatient death.

VITAL SIGNS AS SYMPTOMS

Abnormal vital signs are seldom the fundamental pathophysiologic problem. In shock (Chapter 92), hypotension and tachycardia are manifestations of pathophysiologic processes at cellular and molecular levels. Given the circuitous links from clinical disease to fundamental pathophysiology to abnormal vital signs, it is not surprising that the relationships between the disease states and vital signs are not strong. Until new technologies enable direct measurement of primary pathologic processes, vital signs remain an important, albeit imperfect, proxy.

The five key vital signs are temperature, pulse, blood pressure, respiratory rate, and oxygen saturation (pulse oximetry). Pulse oximetry is included because it has become widely available, is noninvasive, is relatively inexpensive, and provides information unique from the respiratory rate. Advocates have suggested that pain, smoking status, and weight be considered routine vital signs; although a case can be made for each, they are not considered here. Clinicians should never forget that the most important vital sign is what the patient looks like; general appearance is a sign that guides the intensity and urgency of the evaluation.

Oxygen saturation	95-100%	<90%
Systolic blood pressure	90-130 mm Hg	<80 mm Hg, >200 mm Hg
Diastolic blood pressure	60-90 mm Hg	<50 mm Hg, >120 mm Hg

*Normal values are for healthy adults. Values outside these ranges are common in patients who are ill or are anxious about their health care encounter. Panic values demand the health care provider's attention in any adult patient. These values are specific (rarely present in healthy patients at rest) but not sensitive (most ill patients' vital signs will not include panic values). All vital signs must be interpreted in the context of the patient's presentation (see text).

PREDICTIVE VALUE

How can it be that vital signs are poor predictors of diagnoses but central to the practice of medicine? First, although vital signs are insufficiently predictive to be of use in rigid algorithms, these algorithms are but one of several heuristics used by physicians to diagnose and to treat patients. Pattern recognition and the hypothetical-deductive model are heuristics that are based not on average tendencies of a single factor (e.g., hypotension is present in *x*% of cases of septic shock) or a small number of factors (e.g., hypotension and tachycardia are present in *y*% of cases of septic shock) but on the complex interaction of multiple factors (e.g., because this patient is an ill-appearing elderly man with an enlarged prostate and a history of urinary tract infections, is tachycardic and hypotensive, has clear lungs and an enlarged but nontender prostate, and has an oxygen saturation of 97%, he should be treated for urosepsis [Chapter 263] while awaiting results of urinalysis and urine culture). Thus, vital signs can play an important function in medical decision making even though their likelihood ratios for specific conditions are unimpressive.

Despite their poor predictive value for any single diagnosis, abnormal vital signs help identify patients who are sicker.[1] For example, even one abnormal vital sign in the emergency department significantly increases the likelihood of adverse outcomes in elderly patients by about 50%. Abnormal vital signs on emergency department discharge increase the chance of rapid readmission, and abnormal vital signs after admission carry a 20-fold increased risk for subsequent important deterioration. Abnormal vital signs are also a key predictor of which patients are at risk of dying soon after being sent home from an emergency department or after an inpatient admission.[2]

The usefulness of vital signs is also evidenced by the finding that more severe abnormalities are associated with an even worse prognosis. For example, among hospitalized patients, one critically abnormal vital sign carries about a 1% risk for inpatient death, whereas three simultaneously abnormal vital signs carry nearly a 25% risk for inpatient death.

VITAL SIGNS AS SYMPTOMS

Abnormal vital signs are seldom the fundamental pathophysiologic problem. In shock (Chapter 92), hypotension and tachycardia are manifestations of pathophysiologic processes at cellular and molecular levels. Given the circuitous links from clinical disease to fundamental pathophysiology to abnormal vital signs, it is not surprising that the relationships between the disease states and vital signs are not strong. Until new technologies enable direct measurement of primary pathologic processes, vital signs remain an important, albeit imperfect, proxy.

The five key vital signs are temperature, pulse, blood pressure, respiratory rate, and oxygen saturation (pulse oximetry). Pulse oximetry is included because it has become widely available, is noninvasive, is relatively inexpensive, and provides information unique from the respiratory rate. Advocates have suggested that pain, smoking status, and weight be considered routine vital signs; although a case can be made for each, they are not considered here. Clinicians should never forget that the most important vital sign is what the patient looks like; general appearance is a sign that guides the intensity and urgency of the evaluation.

ABSTRACT

Vital signs are a cornerstone of patient care. Critical abnormalities in vital signs require a rapid medical response. Other abnormalities could be completely benign, an indication of an underlying condition that requires diagnosis, or an early warning that a patient is about to decompensate. Given this wide range of significance, physicians must be aware of their patients' vital signs and think about the implications of any abnormalities. Although no simple algorithms can determine decision making, this chapter provides a general differential diagnosis for each abnormality, as well as guidance regarding the initial response to specific abnormalities.

decision making

MEASURING VITAL SIGNS

Although obtaining vital signs is generally straightforward, the validity and reliability of measurement depend on proper technique and, for blood pressure and pulse oximetry, well-maintained equipment. In an era of increasing telehealth, in part because of the severe acute respiratory syndrome coronavirus 2 pandemic (Chapter 336), vital signs increasingly may be measured via home devices, including wearable sensors.[3]

Rectal and oral temperatures are generally accurate (Chapter 259), although oral temperatures can be falsely depressed in patients who breathe through their mouths. Axillary temperature is unreliable and should not be used. There is wide variability in the validity and reliability of measurements performed with tympanic membrane thermometers. A hypothermia thermometer is preferred in patients with suspected hypothermia, and core temperature should be measured with an esophageal, bladder, or rectal temperature sensor in patients with severe hypothermia or hyperthermia (Chapter 95).

Blood pressure must be measured with an appropriately sized cuff (Chapter 64). Automated blood pressure machines occasionally provide spurious results, and questionable values should be confirmed by manual auscultation and by checking other limbs. Pulse is best obtained by palpation because this technique provides the opportunity to assess regularity and contour; the pulse should be counted for sufficient time for an accurate rate to be obtained (at least 15 seconds). High heart rates or dysrhythmias detected on the digital readout of a cardiac monitor, whether watched near the patient, by off-site standardized cardiac telemetry, or a wearable electronic device,[4] must be confirmed by palpation because these monitors can spuriously count large P waves, T waves, or pacemaker spikes as R waves, thereby reporting a heart rate double the actual rate. Orthostatic vital signs—the comparison of blood pressure and pulse in the supine, sitting, and standing positions—are advocated by some but have proved to be insensitive and nonspecific for hypovolemia. Some degree of orthostatic hypotension is also common in patients whose hypertension (Chapter 64) is treated intensively but should not be a reason for de-escalating treatment unless required by the patient's symptoms.[5]

Because the typical respiratory rate is between 12 and 20 breaths per minute and because there is considerable breath-to-breath variation, the respiratory rate should be assessed for at least 30 seconds and preferably 1 minute. New technologies purporting to measure the respiratory rate have not proved clinically useful. Oxygen saturation is dependent on technology, so an understanding of the idiosyncrasies of the device being used is critical. Valid measurements are unlikely unless there is good correlation of the machine's pulse reading and the patient's pulse, and smartphone pulse oximetry readings are often unreliable.[6] The probe should be placed on a part of the body that is warm and well perfused. Pulse oximeters compare the absorption of light at two wavelengths, so readings may be spuriously high under conditions that change the color of oxygenated or deoxygenated hemoglobin, including carbon monoxide poisoning (Chapter 82), methemoglobinemia (Chapter 147), some of the less common hemoglobinopathies, and skin pigmentation. For example, pulse oximetry also slightly overestimates oxygen saturation in Black patients.[7]

ROLE OF VITAL SIGNS IN MANAGEMENT OF THE PATIENT

Abnormal vital signs should be remeasured. Certain abnormalities require prompt evaluation (Table 7-2). Other vital sign abnormalities should be rechecked in the future unless they have been previously noted, in which case a work-up can be initiated, guided by the patient's past history and physical examination findings. It is critical that physicians always "treat the patient, not the vital signs."

PATIENTS WITHOUT SYSTEMIC COMPLAINTS

In patients presenting for a routine evaluation or nonsystemic complaint (e.g., knee injury), an abnormal vital sign will seldom be the harbinger of acute illness. Most commonly, an abnormal vital sign will be a false reading or a transient finding due to random variation, pain, or anxiety that requires no evaluation or treatment and can be rechecked in the future. On occasion, an abnormal vital sign will be the only or most apparent manifestation of a chronic condition or risk factor. The measurement of an elevated blood pressure leading to a diagnosis of hypertension is the classic example of the value of vital signs in such patients.

PATIENTS WHO COMPLAIN OF SYSTEMIC ILLNESS BUT DO NOT APPEAR TO BE VERY ILL

Vital signs serve two additional roles in symptomatic patients who do not appear particularly ill. First, abnormalities in vital signs provide information that may suggest or support a diagnosis. The presence of elevated temperature in a patient with productive cough, shortness of breath, and localized rales and egophony supports a diagnosis of infectious pneumonia. Vital signs may also play a role in defining therapy and triage. For example, guidelines for patients with community-acquired pneumonia (Chapter 85) formally incorporate vital signs.

The second role of vital signs in the stable symptomatic patient is to provide warning that the patient is sicker than they appear. For example, the presence of hypotension in a well-appearing patient thought to have pyelonephritis may be an indication of sepsis or hypovolemia. For vital signs to be of use, the physician must be aware of them and must incorporate them explicitly into a thought process that considers the dangerous diagnoses associated with the abnormal vital sign. The physician then must decide whether the likelihood of each potentially dangerous diagnosis is high enough to warrant specific evaluation. Unfortunately, no quick or easy rules differentiate spurious abnormalities that can be ignored from those that should trigger additional testing or treatment. What can be said is that the well-trained physician who is aware of abnormal vital signs and is willing to contemplate a change in treatment or disposition, sometimes as stimulated by automated alert systems,[8] in response to them is less likely to make mistakes.

A few specific points bear mention. First, for most vital signs, "normal" is relative. Blood pressure must be interpreted in the context of the patient. For example, a blood pressure of 88/64 mm Hg may be reasonable for an otherwise healthy, young 50-kg woman but should cause concern in a 90-kg middle-aged man. Similarly, a blood pressure of 128/80 mm Hg would be fine in a 60-year-old man but worrisome in a 34-week pregnant woman. Second, because vital signs are insensitive measures of disease, normal vital signs should not dissuade the physician from pursuing potentially critical diagnoses. For example, young, well-conditioned adults may maintain normal vital signs well into the course of shock.

USE OF VITAL SIGNS IN PATIENTS WHO APPEAR TO BE ILL

For some patients, abnormal vital signs are expected on the basis of their appearance and their symptoms. For patients in extremis, care should proceed according to established guidelines such as Advanced Cardiac Life Support (Chapter 50), Advanced Trauma Life Support, and algorithms for the treatment of shock (Chapters 93 and 94). For hospitalized patients, markedly abnormal vital signs require urgent evaluation (Table 7-3), which in some settings may trigger a rapid response team.[9] For such ill-appearing patients, two processes must occur. In one, the physician, armed with knowledge of the differential diagnosis of each abnormal vital sign and the ability to take a thorough history and to perform an appropriate physical examination, narrows the list of potential diagnoses and decides which are of sufficient probability to warrant evaluation. Simultaneously, the physician considers the list of treatment options for all diagnoses associated with the abnormal vital sign and, before establishing a diagnosis, initiates those treatments for which the potential benefit of prompt administration exceeds potential harms. For example, antibiotics for febrile patients with suspected bacterial infection, hydrocortisone for hypotensive patients at risk for hypoadrenalism (Chapter 208), and thiamine

TABLE 7-2 ABNORMALITIES REQUIRING RAPID EVALUATION IN THE ASYMPTOMATIC PATIENT

An irregularly irregular rapid pulse (if it is not known to be chronic) should trigger an evaluation of the patient's rhythm so that atrial fibrillation can be identified, evaluated, and treated (Chapter 52), thereby decreasing the patient's risk of stroke.
A heart rate above 130 beats per minute always warrants an electrocardiogram to determine the patient's rhythm and a consideration of the differential diagnosis of tachycardia (hypovolemia, anemia, and thyroid disease in particular).
A markedly elevated diastolic blood pressure (e.g., >115 mm Hg) should stimulate an evaluation for hypertensive urgencies (Chapter 64). Note that hypertension in the absence of signs of acute end-organ damage does not require acute treatment, which can reduce intracranial perfusion pressure and cause stroke. Patients with elevated blood pressure should be offered standard evaluation and treatment for chronic hypertension (Chapter 64).
Markedly low pulse or blood pressure in patients receiving cardioactive medications should lead to a confirmation that the patient is truly asymptomatic, an inquiry into the dosing of these medications, and a reconsideration of the regimen.
Markedly low pulse in elderly patients who are not receiving rate-controlling drugs should trigger an evaluation of the patient's cardiac conduction system.
Oxygen saturation below 93% in the absence of known pulmonary problems should prompt an evaluation of the patient's pulmonary status.

Elsevier

TABLE 7-3 ABNORMAL VITAL SIGNS THAT REQUIRE URGENT EVALUATION

Heart rate
- Heart rate < 40 beats/min, especially if symptoms
- Resting heart rate > 140 beats/min

Blood pressure
- Systolic blood pressure < 90 mm Hg or > 30-40 mm Hg below patient's usual stable blood pressure
- Systolic blood pressure > 200 mm Hg for >30 min
- Diastolic blood pressure > 110 mm Hg with symptoms

Respiratory rate
- Respiratory rate < 8 breaths/min or > 35 breaths/min
- New onset of marked dyspnea, compromised airway, cyanosis

Oxygenation
- O_2 saturation < 85% for >5 min (except patients with chronic severe hypoxemia)
- Need for 100% supplemental O_2 or a nonrebreathing O_2 mask

Temperature
- Body temperature < 35° C
- Body temperature > 39° C or associated with acute decompensation

for hypothermic patients at risk for Wernicke encephalopathy (Chapter 384) may improve outcome and are unlikely to cause harm even if the patient does not have the suspected condition. Although early presumptive treatment can be life-saving in selected patients, it should not be abused; physicians must avoid knee-jerk responses that can cause harm. The current COVID-19 pandemic (Chapter 336) provides a useful example of this principle. Early in the pandemic, patients who presented with low pulse oximetry values were reflexively intubated. Only later did it become clear that this approach was not optimal, but that noninvasive ventilation and sometimes putting the patient in the prone position were better responses (Chapter 337).

DIFFERENTIAL DIAGNOSIS AND TREATMENT OPTIONS

Single Abnormal Vital Signs

Because vital signs can be abnormal in virtually any disease process, no differential diagnosis can be encyclopedic. The physician should focus initially on common diseases and diseases that require specific treatment. The thought process should begin with the chief complaint and history, and then it should incorporate information about the vital signs and the remainder of the physical examination.

Multiple Abnormal Vital Signs

Patients who are acutely ill are likely to have several abnormal vital signs. Although certain patterns of abnormal vital signs predominate in specific conditions (e.g., hypotension, tachycardia, and hypothermia in profound sepsis), no pattern can be considered pathognomonic. The physician's goal is to work toward a diagnosis while simultaneously providing treatments whose benefits outweigh potential harms.

Fever is generally accompanied by tachycardia, with the general rule of thumb that the heart rate will increase by 10 beats per minute for every 1° C increase in temperature. The absence of tachycardia with fever is known as pulse-temperature dissociation and has been reported in typhoid fever (Chapter 284), legionnaires disease (Chapter 290), babesiosis (Chapter 324), Q fever (Chapter 302), infection with *Rickettsia* spp. (Chapter 302), malaria (Chapter 316), leptospirosis (Chapter 298), pneumonia caused by *Chlamydia* spp. (Chapter 294), and viral infections such as dengue fever (Chapter 352), yellow fever (Chapter 351), and other viral hemorrhagic fevers (Chapter 351), although the predictive value of this finding is unknown.

Much can be learned by comparing the respiratory rate with pulse oximetry. Hyperventilation in the presence of high oxygen saturation suggests a central nervous system process or metabolic acidosis rather than a cardiopulmonary process. Low respiratory rates in the presence of low levels of oxygen saturation suggest central hypoventilation (Chapter 74), which may respond to narcotic antagonists.

Hypertension and bradycardia in the obtunded or comatose patient are known as the Cushing reflex, a relatively late sign of elevated intracranial pressure. Physicians should strive to diagnose and treat this condition before the Cushing reflex develops.

APPROACH TO ABNORMALITIES OF SPECIFIC VITAL SIGNS

Elevated Temperature

Normal temperature is often cited as 37° C (98.6° F), but there is considerable diurnal variation and variation among individuals.[10] Furthermore, data suggest that normal human body temperature is now closer to 36.1° C (97° F),[11] so 38° C is the most commonly cited threshold for fever. Fever thought to be due to infection should be treated with antipyretics and appropriate antimicrobials (Chapter 259). The importance of early administration of antibiotics to potentially septic patients cannot be overstated (Chapters 259 and 260). Hyperthermia (temperature above 40° C) should be treated with cooling measures such as ice packs, cool misting in front of fans, cold gastric lavage, and, for medication-related syndromes, medications such as dantrolene (Chapter 95). Most hospital anesthesia departments will have a designated kit for the treatment of malignant hyperthermia (Chapter 400).

Low Temperature

The treatment of hypothermia is guided by its cause (Chapter 95). The body's temperature decreases when heat loss exceeds heat production. Every logically possible mechanism for this phenomenon has been observed. Decreased heat production can result from endocrine hypofunction (e.g., Addison disease [Chapter 208], hypopituitarism [Chapter 205], hypothyroidism [Chapter 207]) and loss of the ability to shiver (e.g., drug-induced or neurologic paralysis or neuromuscular disorders). Malfunction of the hypothalamic regulatory system can be due to hypoglycemia (Chapter 210) and a variety of central nervous system disorders (Wernicke encephalopathy [Chapter 384], stroke [Chapter 376], tumor [Chapter 175], and trauma [Chapter 368]).[12] Resetting of the temperature set point can occur with sepsis. Increased heat loss can be due to exposure, behavioral and physical disorders that prevent the patient from sensing or responding to cold, skin disorders that decrease its ability to retain heat, and vasodilators (including ethanol). A careful history and physical examination should illuminate which of these possibilities is most likely.

Several considerations are worthy of emphasis. The spine of an obtunded hypothermic patient who is "found down" must be protected and evaluated because paralysis from a fall may have prevented the patient from seeking shelter and may have diminished the ability to produce heat. The physician should not forget to administer antibiotics to patients who may be septic (Chapter 94), thiamine to those who may have Wernicke encephalopathy (Chapter 384), hydrocortisone to those who may be hypoadrenal (Chapter 208), and thyroid hormone to those who may have myxedema coma (Chapter 207). Severely hypothermic patients (Chapter 95) should be treated gently because any stimulation may trigger ventricular dysrhythmias; even in the absence of pulses, cardiopulmonary resuscitation should be used only in patients with ventricular fibrillation or asystole.

Elevated Heart Rate

The rate, rhythm, and electrocardiogram differentiate sinus tachycardia from tachyarrhythmias (Chapters 49, 50, 52, and 53). Tachyarrhythmias can be instigated by conditions that may require specific treatment (e.g., sepsis [Chapter 94], electrolyte disorders [Chapters 102, 103, and 104], endocrine disorders [Chapter 202], and poisonings [Chapters 20 and 96]) before the arrhythmia is likely to resolve. For sinus tachycardia, treatment of the underlying cause is always paramount. Treatments may include antipyretics (for fever); anxiolytics; oral or intravenous fluids (for hypovolemia); nitrates, angiotensin-converting enzyme inhibitors, and diuretics (for heart failure and fluid overload [Chapter 46]); oxygen (for hypoxemia); α-blockers (for stimulant overdose); β-blockers (for acute coronary syndromes [Chapters 57 and 58] or thyroid storm [Chapter 207]); and lysis or anticoagulation (for pulmonary embolism [Chapter 68]). Tachycardia is often an appropriate response to a clinical condition and should not be treated routinely unless it is causing or is likely to cause secondary problems.

Low Pulse

Bradycardia (Chapter 51) can be physiologic (athletes and others with increased vagal tone), due to prescribed cardiac medications (e.g., β-blockers, calcium-channel blockers, digoxin), overdoses (e.g., cholinergics, negative chronotropic agents), disease of the cardiac conducting system, electrolyte abnormalities (severe hyperkalemia), and inferior wall myocardial infarction (Chapters 51 and 58). Asymptomatic patients do not require immediate treatment. The goal of therapy is to produce a heart rate sufficient to perfuse the tissues and alleviate the symptoms (Chapter 50). Overdoses should be treated with specific antidotes (Chapter 96). Endocrine disorders should be treated with replacement therapy. In patients with acute coronary syndrome (Chapter 57), the goal is to restore perfusion and alleviate the ischemia. Patients with profound bradycardia or hypotension may require chronotropic drugs to increase perfusion even if these agents increase myocardial oxygen demand. In normotensive patients with milder bradycardia, chronotropic agents should be used only if

symptoms and ischemia cannot be resolved by other means. Atropine is the primary therapy for bradycardia; isoproterenol and cardiac pacing are reserved for those who do not respond (Chapter 51).

Elevated Blood Pressure

Elevated blood pressure does not require acute treatment in the absence of symptoms or signs of end-organ damage (Chapter 64). In patients whose blood pressure is markedly above their baseline, the history and physical examination should assess for the conditions that define "hypertensive emergency": evidence of encephalopathy, intracranial hemorrhage, ischemic stroke, heart failure, pulmonary edema, acute coronary syndrome, aortic dissection, renal failure, and preeclampsia. In the absence of these conditions, treatment should consist of restarting or adjusting the medications of patients with known hypertension and initiating a program of blood pressure checks and appropriate evaluation for those with no prior history of hypertension (Chapter 64).

The patient with a true hypertensive emergency should be treated with agents appropriate for the specific condition. Because rapid decreases in blood pressure can be as deleterious as the hypertensive state itself, intravenous agents with short half-lives, such as nitroprusside, labetalol, nitroglycerin, and esmolol, are preferred (Chapter 64).

Low Blood Pressure

Low blood pressure must be evaluated in the context of the patient's symptoms, general appearance, and physical examination findings. Treatment depends on context. The same blood pressure value may necessitate intravenous inotropic agents in one patient and no treatment in another.

In tachycardic hypotensive patients, the physician must rapidly integrate all available evidence to determine the patient's volume state, cardiac function, vascular capacitance, and the primary cause of the tachycardia (Chapter 92).[13] Not all patients with hypotension and tachycardia are in shock, and not all patients in shock will have hypotension and tachycardia. Point-of-care ultrasound (Chapter 39)[14] of the heart and inferior vena cava may be useful in differentiating the cause of shock.

Treatment of shock is based on the cause: hypovolemic, cardiogenic, or distributive (septic, neurogenic, anaphylactic) (Chapters 92 to 94). Symptomatic hypotensive patients thought to be intravascularly volume depleted should have their legs raised and receive intravenous fluid resuscitation with crystalloid or blood, depending on their hemoglobin level (Chapter 92).[15] In patients with known heart disease, patients who are frail or elderly, and patients whose volume status is uncertain, small boluses of fluid (e.g., 250 mL of normal saline), each followed by reassessment, are preferred so that iatrogenic heart failure may be avoided. Inotropic support should be reserved for patients who do not respond to fluid resuscitation. High-output heart failure should be kept in mind in patients with possible thyroid storm or stimulant overdose.

Increased Respiratory Rate

Tachypnea is a normal response to hypoxemia (see later) or acidemia (Chapter 104).[16] Treatment of tachypnea in the absence of hypoxemia is directed at the underlying cause, which often is pain (Chapter 26). Anxiolytics (e.g., diazepam, 5 to 10 mg PO or IV; lorazepam, 1 to 2 mg PO, IM, or IV) or reassurance can calm patients with behavioral causes of hyperventilation. Breathing into a paper bag has been shown to be an ineffective treatment. Pulmonary embolism (Chapter 68) does not necessarily reduce the oxygen saturation or cause a low Po_2 and should always be considered in at-risk patients with unexplained tachypnea.

Decreased Respiratory Rate

Any perturbation of the respiratory center in the central nervous system can slow the respiratory drive (Chapter 74). Narcotics and other sedatives and neurologic conditions are common causes of a decreased respiratory rate. The primary treatment of apnea is mechanical ventilation (Chapter 91), but narcotic antagonists can be tried in patients with a history or physical examination findings (miosis, track marks, opioid patch) suggestive of narcotic use or abuse (Chapter 365). In nonapneic patients, mechanical ventilation, either noninvasive or invasive (intubation), is indicated for patients who are breathing too slowly to maintain an acceptable oxygen saturation and for patients who are retaining carbon dioxide in quantities sufficient to depress mental function. Patients who are unable to protect their airway should be intubated. Oxygen should be administered to all hypopneic patients who are hypoxemic (see earlier). Patients with chronic hypoventilation (Chapter 74) may have retained HCO_3^- to compensate for an elevated Pco_2 and so may depend on hypoxia to maintain respiratory drive; in these patients, overaggressive administration of oxygen can decrease the respiratory rate, increase the Pco_2, and increase obtundation (Chapter 90).

Decreased Oxygen Saturation

In hypopneic patients, initial efforts should try to increase the respiratory rate (see earlier) and tidal volume. Regardless of etiology, oxygen, in amounts adequate to restore adequate oxygen saturation (Po_2 > 60 mm Hg, oxygen saturation > 90%), is the mainstay of therapy. When oxygen alone fails, noninvasive methods for improving ventilation or tracheal intubation are required (Chapter 90). Oxygen should increase the Po_2 in all patients except those who have severe right-to-left shunting (Chapter 55). Treatment of conditions that cause hypoxemia includes antibiotics (pneumonia), bronchodilators (asthma, chronic obstructive pulmonary disease), diuretics and vasodilators (pulmonary edema), anticoagulants (pulmonary embolism), hyperbaric oxygen (carbon monoxide poisoning), methylene blue (methemoglobinemia, sulfhemoglobinemia), and transfusion (anemia).

8 STATISTICAL INTERPRETATION OF DATA FOR CLINICAL DECISION MAKING

THOMAS H. PAYNE

Statistical techniques are core to evidence-based medicine. The scientific method is based on generating a hypothesis and designing an experiment to test that hypothesis. This powerful approach has been at the root of advances in human endeavors and particularly within medicine. A clear description of a question, a formulation of a hypothesis, a careful design of an experiment to test the hypothesis, the gathering of unbiased data, and the appropriate analysis of the results of the experiment permit the determination of whether a test or treatment is useful or not. If these steps are not conducted in a rigorous manner, statistical tests are likely to produce inaccurate or unreliable results.

INCIDENCE AND PREVALENCE

Incidence describes the number of subjects who *contract* a disease *over time* divided by the population at risk. Incidence is usually expressed as a rate (e.g., 7 per 1000 per year), but it may sometimes be a proportion, as in lifetime incidence. *Prevalence* describes the number of subjects who *have* a disease at *one point in time* divided by the population at risk; it is always a proportion. At any point in time, the prevalence of a disease is defined by the product of incidence of the disease multiplied by the average duration of the disease.

INTERPRETING DATA

Physicians are continuously confronted with data from many sources, including clinical measurements (e.g., vital signs), laboratory tests, and imaging studies. In fact, the work of the modern-day physician is in many respects one of information management. Although the physician may not conduct independent statistical analyses unaided, knowledge of the fundamentals of data analysis is critical for the ability to evaluate whether and how to integrate information into clinical practice.

This knowledge is also essential for understanding the medical literature and incorporating it into practice. Millions of research articles are published each year, and their quality varies widely. Articles published in the leading medical journals undergo rigorous statistical review, but the same is not true for most other journals. Although it generally is inadvisable to base clinical decisions upon a single study, physicians are often confronted with new information and the dilemma of how to deal with it.

symptoms and ischemia cannot be resolved by other means. Atropine is the primary therapy for bradycardia; isoproterenol and cardiac pacing are reserved for those who do not respond (Chapter 51).

Elevated Blood Pressure

Elevated blood pressure does not require acute treatment in the absence of symptoms or signs of end-organ damage (Chapter 64). In patients whose blood pressure is markedly above their baseline, the history and physical examination should assess for the conditions that define "hypertensive emergency": evidence of encephalopathy, intracranial hemorrhage, ischemic stroke, heart failure, pulmonary edema, acute coronary syndrome, aortic dissection, renal failure, and preeclampsia. In the absence of these conditions, treatment should consist of restarting or adjusting the medications of patients with known hypertension and initiating a program of blood pressure checks and appropriate evaluation for those with no prior history of hypertension (Chapter 64).

The patient with a true hypertensive emergency should be treated with agents appropriate for the specific condition. Because rapid decreases in blood pressure can be as deleterious as the hypertensive state itself, intravenous agents with short half-lives, such as nitroprusside, labetalol, nitroglycerin, and esmolol, are preferred (Chapter 64).

Low Blood Pressure

Low blood pressure must be evaluated in the context of the patient's symptoms, general appearance, and physical examination findings. Treatment depends on context. The same blood pressure value may necessitate intravenous inotropic agents in one patient and no treatment in another.

In tachycardic hypotensive patients, the physician must rapidly integrate all available evidence to determine the patient's volume state, cardiac function, vascular capacitance, and the primary cause of the tachycardia (Chapter 92).[13] Not all patients with hypotension and tachycardia are in shock, and not all patients in shock will have hypotension and tachycardia. Point-of-care ultrasound (Chapter 39)[14] of the heart and inferior vena cava may be useful in differentiating the cause of shock.

Treatment of shock is based on the cause: hypovolemic, cardiogenic, or distributive (septic, neurogenic, anaphylactic) (Chapters 92 to 94). Symptomatic hypotensive patients thought to be intravascularly volume depleted should have their legs raised and receive intravenous fluid resuscitation with crystalloid or blood, depending on their hemoglobin level (Chapter 92).[15] In patients with known heart disease, patients who are frail or elderly, and patients whose volume status is uncertain, small boluses of fluid (e.g., 250 mL of normal saline), each followed by reassessment, are preferred so that iatrogenic heart failure may be avoided. Inotropic support should be reserved for patients who do not respond to fluid resuscitation. High-output heart failure should be kept in mind in patients with possible thyroid storm or stimulant overdose.

Increased Respiratory Rate

Tachypnea is a normal response to hypoxemia (see later) or acidemia (Chapter 104).[16] Treatment of tachypnea in the absence of hypoxemia is directed at the underlying cause, which often is pain (Chapter 26). Anxiolytics (e.g., diazepam, 5 to 10 mg PO or IV; lorazepam, 1 to 2 mg PO, IM, or IV) or reassurance can calm patients with behavioral causes of hyperventilation. Breathing into a paper bag has been shown to be an ineffective treatment. Pulmonary embolism (Chapter 68) does not necessarily reduce the oxygen saturation or cause a low Po_2 and should always be considered in at-risk patients with unexplained tachypnea.

Decreased Respiratory Rate

Any perturbation of the respiratory center in the central nervous system can slow the respiratory drive (Chapter 74). Narcotics and other sedatives and neurologic conditions are common causes of a decreased respiratory rate. The primary treatment of apnea is mechanical ventilation (Chapter 91), but narcotic antagonists can be tried in patients with a history or physical examination findings (miosis, track marks, opioid patch) suggestive of narcotic use or abuse (Chapter 365). In nonapneic patients, mechanical ventilation, either noninvasive or invasive (intubation), is indicated for patients who are breathing too slowly to maintain an acceptable oxygen saturation and for patients who are retaining carbon dioxide in quantities sufficient to depress mental function. Patients who are unable to protect their airway should be intubated. Oxygen should be administered to all hypopneic patients who are hypoxemic (see earlier). Patients with chronic hypoventilation (Chapter 74) may have retained HCO_3^- to compensate for an elevated Pco_2 and so may depend on hypoxia to maintain respiratory drive; in these patients, overaggressive administration of oxygen can decrease the respiratory rate, increase the Pco_2, and increase obtundation (Chapter 90).

Decreased Oxygen Saturation

In hypopneic patients, initial efforts should try to increase the respiratory rate (see earlier) and tidal volume. Regardless of etiology, oxygen, in amounts adequate to restore adequate oxygen saturation (Po_2 > 60 mm Hg, oxygen saturation > 90%), is the mainstay of therapy. 8 STATISTICAL INTERPRETATION OF DATA FOR CLINICAL DECISION MAKING

THOMAS H. PAYNE

Statistical techniques are core to evidence-based medicine. The scientific method is based on generating a hypothesis and designing an experiment to test that hypothesis. This powerful approach has been at the root of advances in human endeavors and particularly within medicine. A clear description of a question, a formulation of a hypothesis, a careful design of an experiment to test the hypothesis, the gathering of unbiased data, and the appropriate analysis of the results of the experiment permit the determination of whether a test or treatment is useful or not. If these steps are not conducted in a rigorous manner, statistical tests are likely to produce inaccurate or unreliable results.

INCIDENCE AND PREVALENCE

Incidence describes the number of subjects who *contract* a disease *over time* divided by the population at risk. Incidence is usually expressed as a rate (e.g., 7 per 1000 per year), but it may sometimes be a proportion, as in lifetime incidence. *Prevalence* describes the number of subjects who *have* a disease at *one point in time* divided by the population at risk; it is always a proportion. At any point in time, the prevalence of a disease is defined by the product of incidence of the disease multiplied by the average duration of the disease.

INTERPRETING DATA

Physicians are continuously confronted with data from many sources, including clinical measurements (e.g., vital signs), laboratory tests, and imaging studies. In fact, the work of the modern-day physician is in many respects one of information management. Although the physician may not conduct independent statistical analyses unaided, knowledge of the fundamentals of data analysis is critical for the ability to evaluate whether and how to integrate information into clinical practice.

This knowledge is also essential for understanding the medical literature and incorporating it into practice. Millions of research articles are published each year, and their quality varies widely. Articles published in the leading medical journals undergo rigorous statistical review, but the same is not true for most other journals. Although it generally is inadvisable to base clinical decisions upon a single study, physicians are often confronted with new information and the dilemma of how to deal with it.

ABSTRACT

An important and common element of the physician's role is to make decisions. Effective decision making includes gathering information, determining whether more information is worth the additional risk and expense, and interpreting results. All of these tasks depend on a physician's skill in using data optimally. Information gathering begins with the most important data: those derived from a careful patient history and physical examination. However, the variety of available laboratory tests and diagnostic procedures greatly increases the amount of information that can be obtained and that must be ordered intelligently and interpreted correctly. Appropriate use of clinical information can make important differences in patients' outcomes and in the resources required to optimize them.

KEYWORDS

clinical decision making
biostatistics

Both of these goals—interpreting clinical data and understanding the medical literature—require familiarity with the laws of probability and the field of statistics.

DATA AND THEIR CHARACTERISTICS

Variability is a constant of nature. Statistical techniques represent an effort to describe data and distinguish differences that reflect random variation from those that represent true differences. First, it is necessary to define the nature of data elements being analyzed. Numeric data can vary over a wide range, with values anywhere between the extremes of that range. Blood pressure, for example, can have values of 130, 129.3, 75, and any value in between. Such data are called *continuous*. Numeric data that can only have an integer value, such as number of siblings, are called *discrete*. Other data are reasonable only if they fall into one of several categories, such as whether someone is alive or dead. These data are *categorical*. Labeling a test as positive or negative, which may depend on a somewhat judgmental threshold rather than a continuum, is another example of categorical data.

The next step in examining data is to assess how they are distributed. The distribution of values within a population (e.g., blood pressures) is often categorized as normal (i.e., Gaussian). A normal distribution is often characterized using both measures of *central tendency* (i.e., mean, median, and mode) and measures of *dispersion* around the center of the distribution (e.g., standard deviation). However, many phenomena in medicine produce distributions that are not normal (e.g., Poisson, binomial, etc.), and their analysis requires non-parametric approaches.[1]

HYPOTHESIS TESTING

In medical research, the goal is typically to discern whether two groups differ in a meaningful way, such as whether an outcome in a group that received a particular treatment differs from the outcome in a group that received no treatment or a placebo. This comparison begins with a hypothesis that is stated formally as the *null hypothesis* and is phrased in relation to an alternative hypothesis. The two hypotheses are mutually exclusive and exhaustive. So if a study compares change in blood pressure between a group that received an intervention and one that did not (controls), the null hypothesis would be that the intervention had no effect on blood pressure and the alternative hypothesis would be that it did have an effect.

A study should be designed to determine whether to accept or reject the null hypothesis. In the analysis of data collected in the study, the challenge is to determine whether differences seen in the distribution of blood pressure in people who received the treatment differed from those who did not; and if there is a difference, whether that difference is due to chance. The appropriate techniques for testing hypotheses vary depending on the nature of the data that are collected (Table 8-1).

Since blood pressure measurements vary, any true difference between intervention subjects and control subjects may be difficult to detect if there is only a small number of study subjects; the natural, biologic dispersion of blood pressure may obscure a true difference between the two. However, if the number of subjects is increased, the ability to detect a true difference also increases, and some number should be sufficient to detect a meaningful difference if it truly exists. Below that number, the study may fail to detect a difference between blood pressure readings of the intervention and control groups even though a difference genuinely exists. This level is termed *beta* and represents the probability of a *Type II error* (i.e., failure to detect a true difference when one truly exists). When the number of subjects exceeds the minimum number, there can be greater confidence that a difference will be observed if one truly exists. The probability below which the null hypothesis can be rejected is termed the *alpha* level and represents the probability of rejecting the null hypothesis when the null hypothesis is actually true. A *Type I error* occurs when a null hypothesis is rejected although it is true. To eliminate any possibility of a Type I error would necessitate an infinite number of subjects, so by convention, a 5% or lower chance of this error is considered acceptable. Thus, at an alpha level of 0.05, a difference that is detected will be a true difference 95% of the time, but 5% of the time a random difference will be mistakenly classified as a true difference.

Because falsely concluding that a difference exists (e.g., concluding that a treatment is helpful when it is actually ineffective) is considered a more serious error than the reverse (concluding that a treatment is ineffective when, in fact, it is potentially helpful), levels for beta error typically are set much lower than those for alpha (e.g., 80%). *Power analysis* is a method for estimating the minimum sample size necessary to detect the minimum difference between groups that is defined as clinically meaningful at a specified alpha level (typically 0.05) and beta level.

TABLE 8-1 TYPES OF VARIABLES AND COMMONLY USED STATISTICAL METHODS

		ASSOCIATED STATISTICAL METHODS	
TYPE OF OUTCOME VARIABLE	**EXAMPLES**	**BIVARIATE**	**MULTIVARIATE**
Categorical (dichotomous)	Alive; readmission to the hospital within 30 days	2 × 2 table, chi-square analysis	Logistic regression
Categorical (nominal)	Race; cancer, tumor type	Chi-square analysis	Nominal logistic regression
Categorical (ordinal)	Glasgow Coma Scale	Mann-Whitney-Wilcoxon, Kruskal-Wallis	Ordinal logistic regression
Numerical (continuous)	Cholesterol; SF-36 scales*	*t* Test, analysis of variance	Linear regression
Numerical (count)	Number of times pregnant; number of mental health visits in a year	Mann-Whitney-Wilcoxon, Kruskal-Wallis	Poisson regression, linear models
Time to event regression	Time to breast cancer; time to viral rebound in HIV-positive subjects	Log rank	Cox proportional hazards

*Numerical scores with many values are often treated as though they were continuous.
HIV = human immunodeficiency virus; SF-36 = short-form 36-item health survey.
Courtesy of Thomas B. Newman, MD, MPH, and Charles E. McCulloch, PhD.

P values, which are often reported in medical studies, answer the question, "If the null hypothesis were true, what would be the probability of obtaining, by chance alone, a value of the test statistic this large or larger?" For a fixed level alpha, the power of a test increases with sample size and increases with the true difference between the null hypothesis and a specified alternative.

In essence, the foundation of hypothesis testing is determining whether there is a difference and whether any difference is explained by chance. This determination hinges on probability, as well as conventions regarding tolerance for false-positive (calling a difference real when it actually is a chance effect) and false-negative (not finding a true difference) conclusions.

Study Design

When testing the hypothesis that an intervention is effective, there may be other reasons unrelated to the intervention as to why that outcome measurement might have changed. A *covariate* is another factor, different than the tested intervention, that can potentially influence the outcome under study. For example, in evaluating a medication to treat hypertension, subjects also may have been exposed to a campaign to reduce dietary salt intake. The reduction in salt intake, which could have contributed to any observed changes in blood pressure, would be considered a covariate. It is essential to adjust, or control, for these covariates. The most straightforward way is to assign the intervention to one group but also to measure the change in outcome in an otherwise similar *control* group as well. The strongest research design is the *randomized, double-blinded controlled trial* in which individuals are randomly assigned either to receive the intervention to be tested or to receive an inert or inactive substitute. Subjects in both the intervention and control groups are kept uninformed as to whether they are receiving the active intervention or substitute, and the investigator observing the outcomes is also kept unaware of who is assigned to which group. Thus, neither the subject nor the person recording results knows which arm of the intervention is being observed, and so the reporting and recording of results are insulated from belief in the power of the intervention. This approach is regarded as the most accurate way to assess the effect of an intervention, because any effect of covariates would be expected to occur nearly equally in both the intervention and control groups. Furthermore, any placebo effect is minimized by masking whether or not the subject is receiving the treatment. The advantages of randomized controlled trials make this design the accepted "gold standard" for the evaluation of new pharmacologic treatments.

However, randomized controlled trials are not always practical for many reasons, and much medical knowledge is derived from different study designs

in which it is difficult to know all of the influences on the outcome. Nonrandomized studies can never guarantee adequate control for all covariates, even in very large observational data sets.[2] For example, consider whether hospital mortality rates increased or declined after a large process change, such as the installation of new computer systems to enter and communicate orders. Any changes in error rates may be due to the new computer system, but they also could be explained by heightened awareness of the risk for errors. Investigators can attempt to control for known covariates, but other covariates may not be known. For this reason, randomized trials provide the strongest evidence for causality.

A variety of other *quasi-experimental* study designs have been applied. For example, an intervention might be applied to an entire practice rather than to individual patients. Although it would be ideal to assign the intervention randomly to participating practices, such an approach may be impractical or impossible. One approach would be to introduce an intervention sequentially to individual practices in a systematic manner—which is termed a *stepped wedge* design. If this approach cannot be done in a systematic manner or if the evaluation is being conducted post hoc, the data can be retrospectively segmented into short, consecutive time periods so that the analysis can try to distinguish temporal trends from actual effects of the intervention. This design is termed an *interrupted time-series*.

When evaluating health care interventions, it is often desirable to include both a quantitative measurement of outcomes (such as mortality or hospital admissions) and observational or qualitative methods, such as surveys or structured interviews. These data are often complementary. If, for example, a study fails to show that an intervention was effective, qualitative information may reveal whether it was properly implemented and what problems prevented implementation. Qualitative methods also are important to understand the attitudes and reactions of health care personnel and patients.

Time to Event Data

A common study design is to follow a sample of patients who receive a treatment until a prespecified outcome has occurred, such as death or hospital admission. The analysis uses the time between the subject's participation in the study until the outcome. Results are often displayed graphically as a survival distribution. Some subjects may contribute data to the study but not complete it. A *Kaplan-Meier analysis* allows estimation of survival in a manner that uses data from patients who drop out of the study. A *Cox proportional hazards model* compares the survival between or among groups.[3]

Noninferiority Trials

In some research, the goal is not to find a more effective treatment but one that has other advantages, such as fewer side effects or lower cost. In these studies, called *noninferiority trials*, the purpose is to evaluate a new treatment against an existing one with the goal of demonstrating that it is at least as good. An example is comparing a new treatment with a standard treatment, in which the goal is not to find an approach that is more effective, but to find a therapy that has lower cost or fewer adverse effects with at least similar efficacy to the standard treatment.[4]

CAUSALITY

There is an important difference between association and causality. The rooster's crow is *associated* with, but does not cause, sunrise. Anoxia *causes* death. An investigator's—and the public's—belief that a treatment is beneficial is powerful, and the scientific method can help us determine the difference between belief and reality. Belief can influence biology. The placebo effect is the concept that effects can be due to belief and not to the intervention itself.

Confounding

If a covariate is related to both the outcome and to the exposure or risk factor being studied, and if it is unequally distributed between the groups being compared, it becomes a *confounder*. Since most health outcomes have many contributing causes, there often are many possible confounders. For example, in a study of the association between obesity and heart disease, age may be a confounder. Age is related to obesity and also to heart disease. If the obese subjects are older than the nonobese subjects, then differences in the outcome of heart diseases may be due to the older age of the obese subjects rather than to their obesity.

In observational studies in which randomization is not possible, steps to reduce bias due to confounding should be considered in the analysis. In an observational study of the effect of a treatment on an outcome of interest, it may be that the treatment is given to some subjects (patients) because of their characteristics, such as age or severity of illness. A variety of sophisticated statistical techniques are applied in an effort to reduce bias in observational studies. For example, a *propensity score* is the probability that a study subject would receive the exposure or treatment of interest, based on the subject's characteristics and the clinical environment.[5] Using the propensity score, it is possible to adjust for the effect of known confounding variables so that it is less likely the difference in outcome is due to confounding bias. Nevertheless, all techniques to reduce confounding depend entirely on data about relevant covariates. If such data are missing, statistical adjustment cannot produce an accurate result. A limitation of the propensity score in reducing confounding bias is that many confounders may be unknown or difficult or even impossible to measure.[6]

Machine Learning

Machine learning approaches problems by learning rules from data in contrast with expert systems. Starting with patient-level observations, algorithms sift through vast numbers of variables, looking for combinations that reliably predict outcomes.[7] This process in some ways resembles traditional regression models: there are outcomes, covariates, and statistical functions linking the two. Machine learning can handle enormous numbers of predictors and combine them in nonlinear and highly interactive ways. Optimism for machine learning should be tempered by understanding that association is not the same as causation and that vast biomedical data available to apply to these techniques may have insufficient breadth—lacking, for example, social determinants of health—or insufficient quality or biases that can make the results unreliable or even not valid.[8] Another limitation can be the difficulty in understanding and interpreting results because of the complexity and opacity of the model. Before they are of clinical use, machine learning models must be independently validated in prospective clinical trials in sites other than those in which the model was developed.[9]

STATISTICAL APPROACHES AND CHALLENGES

Multivariable Statistics

In many cases, researchers are interested in the effects of multiple predictor variables on an outcome. Particularly in observational studies, in which investigators cannot assign values of a predictor variable experimentally, it will be of interest to estimate the effects of a predictor variable of interest independent of the effects of other variables.[10] For example, in studying whether breastfeeding reduces a mother's risk for subsequent breast cancer, investigators would try to take differences in age, race, family history, and parity into account. Trying to stratify by all these variables would require a massive data set. Instead, multivariable models are used to enable the information about individual predictors to be summarized using the full data set.

Multiple Comparisons

Analyses in which multiple statistical tests are conducted can lead to a false conclusion that one of them is a positive result. The more tests conducted, the more likely it becomes that one will be positive based on chance alone even though the P value may be set to 0.05. One way to correct for this problem is to use the *Bonferroni correction*, which divides the P value for rejecting the null hypothesis by the number of hypothesis tests performed.[11]

Meta-analysis

Meta-analysis is a statistical method for drawing inferences from a sample of *studies* to derive a summary estimate and confidence interval for a parameter measured by the included studies. Meta-analysis allows for a formal combination of results while estimating and accommodating both the within-study and between-study variations.[12,13]

USING DATA FOR CLINICAL DECISIONS

An important and common element of the physician's role is to make decisions.[14] Effective decision making includes gathering information, determining whether more information is worth the additional risk and expense, and interpreting results. All of these tasks depend on a physician's skill in using data optimally. Information gathering begins with the most important data: those derived from a careful patient history and physical examination. However, the variety of available laboratory tests and diagnostic procedures greatly increases the amount of information that can be obtained and that must be ordered intelligently and interpreted correctly.[15] Appropriate use of clinical information can make important differences in patients' outcomes and in the resources required to optimize them.

TABLE 8-2 PRINCIPLES OF TEST ORDERING AND INTERPRETATION

The interpretation of test results depends on what is already known about the patient.
No test is perfect; clinicians should be familiar with its diagnostic performance and never believe that a test "forces" them to pursue a specific management strategy.
Tests should be ordered if they may provide *additional* information beyond that already available.
Tests should be ordered if there is a reasonable chance that the data will influence the patient's care.
Two tests that provide similar information should not be ordered.
In choosing between two tests that provide similar data, use the test that has lower costs or causes less discomfort and inconvenience to the patient.
Clinicians should seek all of the information provided by a test, not just an abnormal or normal result.
The cost-effectiveness of strategies using noninvasive tests should be considered in a manner similar to that of therapeutic strategies.

Courtesy of Thomas H. Lee, MD.

Evaluating a patient who presents with new breathlessness (Chapter 71) presents an example of decision-making principles. A thorough history and physical examination set the foundation, and a spectrum of choices are considered. Is this a temporary problem or a life-threatening condition for which immediate and potentially risky testing and treatment should be recommended? (Table 8-2) The sequence in which testing is undertaken also has implications for safety and cost. Some tests are simple and fast to perform and most helpful when results are negative; others involve substantial risk and expense but can give a definitive answer.

Theories and Principles Useful in Decision Making

Much of medical practice involves risk and uncertainty. When discussing uncertainty, the concept of *probability* is useful. Probability is the likelihood that something occurs; a probability of 1.0 means it is certain to occur, and a probability of 0 means it will not occur. The term *odds* refers to a ratio of probabilities of an event (p): Odds = p/(1 – p). If the probability of the event is 50% or 1 in 2, as in a coin flip, then odds of the event are 1 (or 1 : 1). If the probability is 1 in 3, or 0.33, then the odds are 0.33/0.66 or one half (1 : 2).

A simple yet instructive model of decision making is a 2 × 2 table (Fig. 8-1). A group (or *population)* of patients is divided into 4 cells. The table shows the presence or absence of a disease across the top and test results on the left. The cells in this 2 × 2 table are labeled with letters beginning with a in the upper left and d in the lower right. The *sensitivity* of a test, which is defined as the probability of positive results when the disease is known to be present, is calculated in the table as a/(a + c). Test *specificity*, which is the probability of a negative test result when the disease is absent, is calculated as d/(b + d). Sensitivity and specificity are referred to as *test characteristics* because they explain how a test performs in the presence or absence of disease. In clinical practice, however, tests are usually used to determine whether a disease or condition is present or absent, or at least how likely it is based on a given test result. In the 2 × 2 table, this probability, which can be calculated as a/(a + b), is referred to as the *positive predictive value*. Similarly, d/(c + d), which is the *negative predictive value* of the test, indicates how likely it is that the disease is absent given a negative test result.

Inspection of this 2 × 2 table shows another very important finding: how common the disease is in this population, shown as (a + c)/(a + b + c + d). This calculation is analogous to the *prevalence* of the disease in the population.

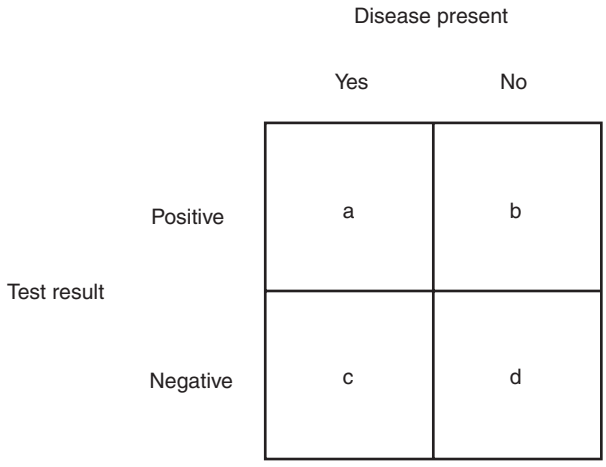
A special insight from this simple 2 × 2 table is that positive and negative predictive values depend on the test characteristics, but importantly they also depend on the prevalence of the disease in this particular population of patients. Different positive and negative predictive values result when the same test is used in a population in which the disease is rare compared with when it is used in a population in which the disease is common.

This insight is the essence of *Bayes theorem*: the likelihood of the disease given a positive test result depends on both the test characteristics and on the prevalence of the disease in the population. Bayes theorem is often expressed by the formula $P(A|B) = (P(B|A) * P(A))/P(B)$, (probability of disease A given test result B is the probability of result B given disease A times the probability of disease A, divided by probability of result B), but the essence of the greatest value of Bayes theorem to physicians can be understood from the simple 2 × 2 table. Bayes theorem also implies that any new information, as from a new research result, should be interpreted in the context of prior knowledge.[16]

Another useful concept is the *likelihood ratio*, which is the prevalence of a sign (or any test result) in patients with the diagnosis of interest divided by the prevalence of the identical finding (or test result) in patients without the target diagnosis. The positive likelihood ratio is expressed by the formula $P(B|A)/P(B|\bar{A})$ (or [sensitivity] ÷ [1 – specificity]) (E-Table 8-1).

Other common measures used in decision making can be derived from these simple building blocks that come from the 2 × 2 table. *Pretest probability* in the 2 × 2 model is the same as the prevalence of disease—how common it is in that population. Before doing any test, the probability of disease is simply the prevalence in that population. After performing the test, the probability may be different—the *post-test probability*—which is why and how the test can be useful.[17]

In the 2 × 2 model, a test is defined as either positive or negative. However, it may not be clear where to draw the line (or threshold) between positive and negative. Fig. 8-2 shows three possible divisions between a positive and negative test result. The vertical line on the left excludes all patients who do not have the disease, but it classifies only half of the patients with the disease as positive. The one on the right results in all patients with the disease having a positive result but at the cost of including half of the patients who do not have the disease in the positive result. The middle line achieves a compromise—most of the patients with the disease are defined as having a positive result, and most of the patients without the disease are defined as having a negative result. Which of the three lines is chosen depends on how the test is being used. A plot of all such possible lines with the sensitivity and specificity creates a curve showing how sensitivity and specificity are related for the test: a *receiver operator characteristic (ROC)* curve. Fig. 8-3 is a common way to display this relationship. An ideal test would have a curve closer to A than to B—a high sensitivity and a high specificity. ROC curves can also be used to compare the ability of different tests to distinguish between the presence or absence of disease. Tests with higher *areas under the curve* are considered better tests.



From these data, one can also calculate:

Risk ratio or relative risk (RR)	$\frac{a}{(a+b)} \div \frac{c}{c+d}$
Relative risk reduction (RRR)	1 – RR
Risk difference or absolute risk reduction (ARR)	$\frac{a}{(a+b)} - \frac{c}{(c+d)}$
Number needed to treat (NNT)	$\frac{1}{ARR}$
Odds ratio (OR)	$\frac{ad}{bc}$

FIGURE 8-1. **A 2 × 2 table evaluating use of a test to determine if a disease is present. In this model, test sensitivity is a/(a + c), specificity is d/(b + d), and disease prevalence is (a + b)/(a + b + c + d). Positive predictive value can then be calculated as a/(a + b) and negative predictive value as d/(c + d).**

E-TABLE 8-1 KEY DEFINITIONS FOR BAYES THEOREM*

Probability	A number between 0 and 1 that expresses an estimate of the likelihood of an event
Odds	The ratio of [the probability of an event] to [the probability of the event's not occurring]
BAYESIAN ANALYSIS	
Pretest (or prior) probability	The probability of a disease before the information is acquired
Post-test (or posterior) probability	The probability of a disease after new information is acquired
Pretest (or prior) odds	(Pretest probability of disease)/(1 – pretest probability of disease)
Likelihood ratio	(Probability of result in diseased persons)/(Probability of result in nondiseased persons)

*Disease can mean a condition, such as coronary artery disease, or an outcome, such as postoperative cardiac complications.

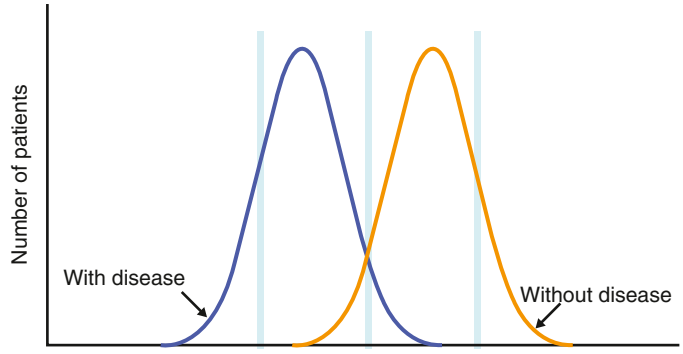


FIGURE 8-2. For each of the vertical lines, those results to the left indicate a positive result, while results on the right indicate a negative result.

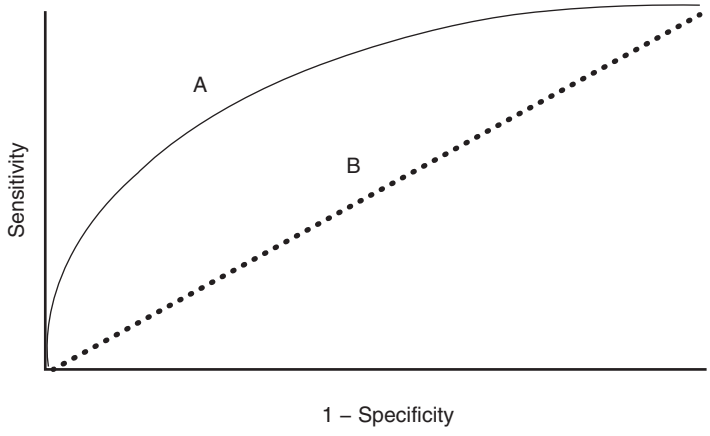

FIGURE 8-3. A receiver operator characteristic (ROC). This curve displays all the possible decision thresholds based on a test's sensitivity and specificity. The best test has very high sensitivity and specificity. In this example, A is a better test than B.

In most cases, physicians do not rely on a single test to determine whether or not a condition or disease is present. Rather, several test results and other data (which may include portions of the patient's history and findings on the physical examination), as well as findings from past records, are incorporated into that judgment. This multiplicity of information highlights one of the limitations of Bayes theorem. The results of multiple tests may not be independent of each other, but Bayes theorem assumes that they are. It is also important to be aware that it is difficult to determine the accuracy of historical and examination data—particularly if not gathered first-hand but obtained from an electronic health record, which may contain errors. Some laboratory, imaging, and pathology results may vary depending on the subjective assessment of the person who creates the report. Astute clinicians understand that data may be inaccurate or subject to differing interpretation.

When should a test be ordered? Gathering additional information—whether from history, repeated examinations, tests, or imaging—can change the likelihood of disease, as is demonstrated by the 2 × 2 table. In general terms, additional data should be obtained only if they would change the likelihood of a disease or condition at an acceptable cost and risk and if such a change in probability would affect what is recommended to the patient. "Will it change therapy?" is a common question that summarizes such thinking: Will the test lead to a diagnosis that would be treated differently? If not, then the value of the test is lower. Sometimes the most important choice is to defer further testing and to observe the patient over time—the "test of time."

Utility

The results of diagnosis and treatment vary, and the importance or value of those outcomes also varies. For example, the value of surviving may depend on quality of life and side effects endured to achieve survival. Quantifying this value can be difficult, but ultimately the most important quantification is from the patient. The term *utility* describes the value or importance of the outcome as judged by the patient or measured in some other way. In some analyses, the length of survival is adjusted by a measure of the quality of life, described as *quality-adjusted life years* or *QALYs*.[18]

DECISION-MAKING STRATEGIES

Shared Decision Making

Physicians make many decisions, some of which are simple and many of which are complex. A good physician does not make all of these decisions independently. Especially for decisions that involve risks or preferences, the wise physician involves the patient in decision making when possible. Shared decision making considers the utility of different outcomes and the patient's desires, which may vary widely from one person to the next. Shared decision making is an important element of physician-patient interaction and also has direct ties to the decision-making process.[19]

Decision Analysis

Answers to some questions involve a series of questions and probabilities that are not practical to answer with a single study or test. As a result, an approach known as *decision analysis* can be useful (E-Fig. 8-1). This analysis begins with a question, such as "should a drug be given?", which then leads to branches stemming from the yes and no answers, each of which has its own branching from what is called a chance node. Chance nodes may lead to other branches. Each chance node has several probabilities that, by definition, must add up to one. The end of each of the branches is assigned a utility. To determine, for example, if a drug should be given, the utility of each end branch is multiplied by the probability of ending on that branch, and this process is continued (or folded back) until each of the original choices is assigned a score. Using this model, the best choice is the choice with the highest score. Decision analysis can be applied to decisions in which prospective trials are impractical, such as a public health policy decision, or when a randomized controlled trial would be impractical, such as developing a strategy for screening for cervical cancer. Since probabilities assigned to some of the nodes may not be known and could plausibly be within a range, a technique known as *sensitivity analysis* can be used to determine if the key conclusions of the decision analysis model would change as the chance node probabilities change within that range. Including benefit and cost in decision analysis permits a cost-benefit (or cost-effectiveness) analysis[20] that can lead to informed decisions regarding what strategy or approach should be pursued, or whether a new technology or treatment should be adopted.

Aids to Decision Making

As the volume of text, test results, images, and genomic data rises, the limitations of human cognition often are reached. For example, most physicians are able to keep several data elements in mind when making a decision, but decision-making aids become worth considering when the number of facts to be considered rises to include a dozen or more. Some of these aids are simple *prediction rules*,[21] which can use clinical data to estimate the pretest probability of a condition. In other cases, automated systems, as simple as smartphone applications and as complex as cloud-based systems, can be helpful for diagnostic and therapeutic decision making. With progressively rising volumes of health care data and computing power, machine learning, artificial intelligence, and other analytical tools and techniques may increasingly provide additional aid to clinician decision making. Periodic modifications of decision aids and testing them using prospective (ideally randomized controlled) trials can increase their value.

To apply these concepts, consider a patient with breathlessness. Does this patient have a pulmonary embolism or some other condition? Although data derived from the history and physical examination individually have a low sensitivity, the pretest probability of pulmonary embolism (Chapter 68) can be classified as high, moderate, or low when used together to calculate a Wells score (Chapter 68). In patients so classified as having low risk, the D-dimer test has high sensitivity and therefore a high negative predictive value; as a result, a negative test reduces the risk of pulmonary embolism substantially. The D-dimer test carries a trivial risk to the patient, and its cost is low. Based on its test characteristics, a negative D-dimer result can safely exclude venous thromboembolism and limit the number of patients requiring further evaluation with imaging techniques. Conversely, in a patient with high pretest probability, a test with higher risk and expense may be warranted, such as computed tomographic pulmonary angiography, which has both a high sensitivity and a high specificity. By balancing the patient's pretest probability, as determined using a prediction rule, with a test's expenses, risks, and operating characteristics, an appropriate decision-making strategy can be developed and applied to an individual patient.

E-FIGURE 8-1. Example of decision analysis. The model begins with a choice (choice node) leading to chance nodes. The probability of branches from each choice node add up to 1. At the end of all branches is an outcome with a utility value. By "folding back" each chance node—adding probability × utility successively—a value is assigned to both choices.

9 MEASURING HEALTH AND HEALTH CARE

CAROLYN M. CLANCY AND ERNEST MOY

Physicians routinely quantify a variety of health measures, including symptoms, vital signs, and findings on physical examination, to improve diagnosis, treatment, and prognostication. Similarly, measures of health care efficacy and quality of health care can and should be prioritized for several reasons.

First, the quality of care delivered is often suboptimal. Persistent variations in practice for patients with the same diagnosis reflect a combination of clinical uncertainty, individualized practice styles, patients' preferences and characteristics (age, race, ethnicity, education, income), and other factors. Both suboptimal care and varied care for the same condition undermine the historical assumption that a combination of highly trained health professionals and accredited facilities is sufficient to ensure consistent high-quality care.

Second, a major challenge in health care today, largely attributable to the successes of biomedical sciences, is the management of chronic disease for a population with an increasing life expectancy. For chronic conditions, health benefits are often and more appropriately measured in improvements in functional status or quality of life, rather than simply using mortality rates or life expectancy.

Third, increasing costs of health care are now threatening public budgets and investments in other social goals, such as education. Although the United States spends more per capita on health care than any other developed nation, the achieved outcomes lag far behind.

Finally, advances in communication and information technologies have inspired more people to play an active role in their health and health care. These innovations have accelerated demands for transparency and shared decision-making.

As health insurance and health care regulation have expanded, requirements to track and justify health care services have grown. Intensifying urgency to improve the quality of health care, reduce disparities, control costs, and enhance transparency will likely lead patients and insurers to demand more data and to link quality measures to payments for services.

Fortunately, modern technology can help to meet the demand for data. Patients can record and submit their health parameters using handheld devices connected to personal health records. Automated billing programs can track health care services, and electronic health records can assess the quality of physician care. Ultimately, fully integrated health information systems will allow patient information to be retrieved instantly and seamlessly whenever and wherever it is needed. For example, the Department of Veterans Affairs has substantial clinical and demographic data on veterans who receive care at their facilities. These data allowed rapid identification and outreach to at-risk groups early in the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) pandemic, so that vaccines could be targeted to patients at need without ethnic, socioeconomic, or geographic disparities.[1] In addition to assessing the quality of care today, these tools offer enormous promise for learning as a byproduct of care delivery.

HOW ARE HEALTH AND HEALTH CARE MEASURED?

Three types of measures typically assess health and health care. Measures of *health* quantify the sickness or well-being of a person. Measures of *health care quality* quantify the extent to which a patient receives needed care and does not receive unnecessary care. Health care quality is assessed using measures of *structure* (e.g., education and credentialing of clinicians), *process* (adherence to professional standards and evidence-based recommendations), and *outcomes* (or end results of care, including how patients experience their care and their self-reported health and function). Measures of *health care resources* quantify the resources used (e.g., imaging, surgery, medication, intensive care) to improve the health of a patient. All measures can be summed across populations within a practice or community (Table 9-1).

Measures of health and health care often overlap (E-Fig. 9-1). Health measures that can be improved by health care, such as blood pressure or blood glucose levels, are often used as health care quality outcome measures. The delivery of quality health care requires the use of resources and the generation of direct health care costs, which may or may not improve health care at the margins of spending. Impaired health that reduces the ability to do work and earn wages but that could have been prevented by the delivery of health care contributes to the indirect costs of health care. At the intersection of health, health care quality, and health care resources are measures of health care value. These measures compare the health benefits of specific health care services with their costs.

WHY MEASURE HEALTH AND HEALTH CARE?

Measures of health and health care can be used for many purposes by different stakeholders (Table 9-2). Patients can use their own health information to track their progress, adjust their lifestyle, and plan for their future health

TABLE 9-1 MEASURES OF HEALTH AND HEALTH CARE

MEASURES OF HEALTH

- *Mortality:* rates of death typically adjusted for age and sex
- *Morbidity:* incidence and prevalence rates of diseases and their sequelae
- *Functional status:* assessments of a patient's ability to perform various actions such as activities of daily living or instrumental activities of daily living as observed by a provider or reported by the patient
- *Self-reported health status:* a patient's assessment of his or her health and well-being

MEASURES OF HEALTH CARE QUALITY

- *Health care outcomes:* the end results or health benefits derived from good health care or the health loss attributable to poor health care
- *Health care processes:* assessments of whether the right care was delivered at the right time and in the right way
- *Health care infrastructure:* the availability of resources needed to deliver high-quality health care
- *Patient perceptions of health care:* a patient's assessment of health care received, usually emphasizing patient-provider communication and shared decision making
- *Access to health care:* the ability of patients to gain entry into health care and navigate to needed resources

MEASURES OF HEALTH CARE RESOURCES

- *Health care utilization:* the quantity of health care services that are used
- *Direct costs:* the costs of providers, supplies, and equipment needed to deliver health care
- *Indirect costs:* the costs of lost wages and decreased productivity due to illness or injury that could have been prevented by appropriate health care
- *Nonmedical costs:* the costs of health care not related to the delivery of services, such as administration, advertising, research, and profits earned by health industries

TYPE OF MEASURE	EXAMPLE
HEALTH	
Mortality	Deaths due to colorectal cancer per 100,000 population
Morbidity	New AIDS cases per 100,000 population
Functional status	% of people unable to perform one or more activities of daily living
Self-reported health status	% of people reporting that their overall health is excellent
HEALTH CARE QUALITY	
Health care outcomes	Deaths per 1000 hospitalizations with pneumonia
Intermediate outcomes	% of adults with diabetes whose blood pressure is <140/80 mm Hg
Health care processes	% of children who were given all recommended vaccinations
Health care infrastructure	% of office-based physicians with computerized systems for recording clinical notes
Patient perceptions of health care	% of patients who always reported good communication with their regular providers
Access to health care	% of patients who were unable or delayed in receiving medical care
HEALTH CARE RESOURCES	
Health care utilization	% of people with an emergency department visit in the past year
Direct costs	Expenditures for the treatment of depression
Indirect costs	Lost wages and productivity while caring for children with asthma
Nonmedical costs	Profits earned by pharmaceutical companies

ABSTRACT

Measuring health, health care quality, and health care resources is an essential dimension of contemporary health care organizations. This chapter describes the different approaches to measurement; the evidence base for those measures; and how to match available measures to the needs and interests of patients, policymakers, and other stakeholders.

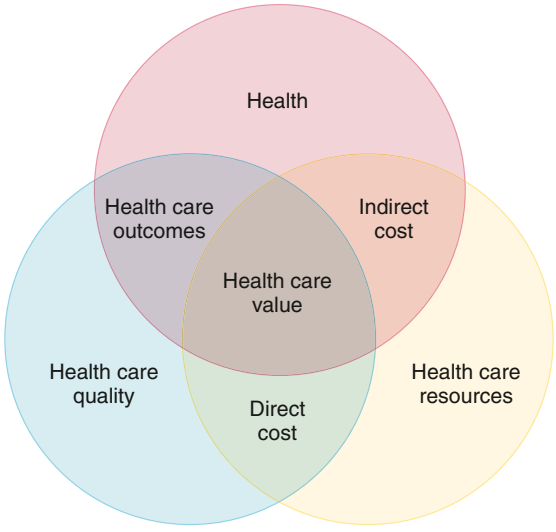
health care quality
health care value
evidence-based health care



E-FIGURE 9-1. **Types of measures of health and health care.**

TABLE 9-2 USES OF HEALTH AND HEALTH CARE MEASURES BY USER AND UNIT OF ANALYSIS

	USES BY PROVIDERS	USES BY POLICYMAKERS	USES BY PATIENTS
Patient-level measures	Diagnosis and prognosis Monitoring treatment response and compliance	Identifying sentinel events	Tracking health and health needs Retirement and estate planning
Provider practice or health plan–level measures	Improving quality Improving efficiency Reducing disparities	Public reporting Paying for performance Provider credentialing	Selecting providers and health plans
Community-level measures	Selecting practice location	Resource allocation Policy evaluation	Selecting place to live

care needs. Patient-level measures are important to physicians, hospitals, health plans, and policymakers, whether they are used to identify sentinel events that represent quality defects (e.g., amputating the wrong leg or giving a patient the wrong medication), to initiate root cause analyses to improve health care quality, or to assess how quality output is linked to cost input (Chapter 10).

Hospitals and health plans aggregate measures over their practices to identify opportunities for raising quality, improving efficiency, and reducing care disparities. For measures for which physicians are primarily accountable, these data can be used to acknowledge and reward high-performing physicians, select physicians for inclusion on panels, and produce report cards to inform the public. Patients can use these report cards to select physicians and health plans that best match their health care needs. Regulators may examine measures to assess qualification for licensure and to identify physicians who might benefit from remedial instruction. Credentialing organizations may construct measures to demonstrate the superior performance of physicians who meet their high standards. For example, the National Committee for Quality Assurance maintains the Healthcare Effectiveness Data and Information Set that is widely used to accredit health plans, and the American Board of Internal Medicine and other specialty boards include measures of practice performance as well as measures of medical knowledge for the maintenance of certification. Measures that are aggregated to the community level can help policymakers allocate health care resources to locales with the greatest need and assess the success of any interventions.

SELECTING MEASURES BASED ON EVIDENCE

Data used to measure the structure, process, and outcomes of health care can be gathered as part of hypothesis-driven research, as a part of quality improvement, or from secondary sources of data initially collected for routine clinical care billing. The data's rigor and integrity are critical to the reliability of analyses performed on them.

In addition to the quality of the data themselves, however, the method of study design is also critical to the validity of reported findings. The most robust measures are supported by the concurrence of evidence derived from different research methodologies. In randomized controlled trials, random assignment of the intervention ensures that both patients who do and do not receive it are as similar as possible. In double-blind studies, neither the patient nor the patient's physician knows the assigned treatment. For more complex interventions, such as the use of a team to manage depression, blinding is impractical. In all settings, controls typically receive the best standard care. In some situations, patients may serve as their own controls in a time-series randomized trial. Adaptive designs incorporate strategies that assign more participants to treatment groups that are performing well, assign fewer participants to groups that are performing poorly, and investigate wide dose ranges to identify the most effective dose.[2] Pragmatic trials inform a clinical or policy decision by determining the usefulness of an intervention for real-world clinical practice. Noninferiority trials are designed to prove the equivalence of two strategies.[3]

Although the randomized trial is a rigorous way to assess treatment effects, enrollment is often limited to selected individuals who meet strict entry criteria. This approach enhances a trial's internal validity but limits its generalizability. As a result, randomized trials are ideal for establishing an intervention's efficacy, which is its potential benefit under ideal conditions, but not necessarily its *effectiveness* in the real world. *Cluster randomized trials*, which randomize the level of the provider or system, represent a practical approach to determining effectiveness.

Although randomized trials are critical for assessing efficacy and effectiveness, *observational* and *case-control* studies are also important. In a *cohort study*, persons or patients are followed to determine their outcomes as a function of whether or not they possess a particular attribute or have been exposed to a particular condition or intervention. Cohort studies can provide a direct estimate of the absolute risk for an outcome in exposed patients but cannot guarantee whether such differences are related to interventions that were not randomly allocated.[4]

In *case-control studies*, cases are defined based on having experienced an outcome not experienced by controls (Chapter 8). Information that is gleaned from existing records or interviews can determine the proportion of case and control patients who experienced an exposure of interest. Case-control studies can achieve the same or higher statistical power as cohort studies despite enrolling fewer subjects, so they are especially attractive for investigating uncommon outcomes, such as serious adverse effects of medications when the events are too rare to study with clinical trials or cohort studies. Case-control studies are subject to misclassification bias and recall bias, and they provide estimates of relative risk but not absolute risk.

Cross-sectional studies collect data at just one point in time. They can be used to estimate the prevalence of a condition or outcome but not to make valid inferences about whether a given outcome is related to any causal attribute or event.

There are additional methodologic issues beyond the credibility and quality of the source of data for quality measures. When presented with reports suggesting less-than-perfect performance, many physicians believe that their patients are sicker or are less likely to adhere to treatment recommendations. To address these concerns, risk adjustment for severity of illness, accurate identification of patient characteristics, and assessment of outcomes over time are all critical. Case-mix adjustment methods commonly use sophisticated statistical approaches (Chapter 8) in an attempt to adjust for such potential differences and to estimate whether observed differences result from differing patient populations rather than true differences in quality of care.[5]

The precision of specific measures is also a challenge. Many stakeholders, especially payers and policymakers, are increasingly impatient and are generally more enthusiastic about the use of measures that are only "pretty good" than are providers whose care is being judged.

SELECTING MEASURES: WHICH MEASURES ARE RIGHT FOR WHAT PURPOSE?

Creating measures is different from selecting which measures are most important and meaningful. Numerous publicly available sources provide a wealth of health and health care information (E-Table 9-1). The most prominent consensus-based organization that endorses measures is the National Quality Forum, which convenes panels of experts to assess the quality of a proposed measure based on criteria that include importance, scientific acceptability, feasibility, and usability. Endorsed measures are reassessed periodically to ensure they remain up-to-date and applicable.

The National Institutes of Health Patient Reported Outcomes Measurement Information System (http://www.nihpromis.org) is a repository of standardized patient-reported health status measures and collection instruments. Domains include physical, mental, and social well-being. The Agency for Healthcare Research and Quality National Quality Measures Clearinghouse (http://www.qualitymeasures.ahrq.gov) is an inventory of evidence-based measures of health care quality. Domains include clinical quality, efficiency,

TABLE 9-3 ATTRIBUTES OF MEASURES OF HEALTH AND HEALTH CARE

MEASURE ATTRIBUTES	CRITERIA FOR PROVIDERS	CRITERIA FOR POLICYMAKERS	CRITERIA FOR PATIENTS
Measure is scientifically sound			
Based on strong evidence	Based on high-quality studies?		
Valid	Measures what is intended and includes key elements?		
Reliable	Reproducible by different measurers and providers?		
Clearly specified	Numerator, denominator, exclusions, and risk adjustment defined?		
Endorsed by independent experts	Well-accepted by scientific and medical communities?		
Condition is important			
Affects many people Causes high mortality or morbidity Is costly Is very unequal across populations	Important for my practice or the population I serve?	Important for population that will be affected by my policy?	Important to me?
Data collection is feasible			
Already available Could be collected at low cost relative to potential benefit Auditable	Available for my practice or the population I serve?	Available before and after policy implementation for affected population?	Available to me?
Findings are actionable			
Can be understood Can be improved Have been used successfully Have few unintended consequences	Do I know what actions I must change to improve quality? Used in practices like mine to improve quality with few unintended consequences?	Do I know what policies I must change to improve quality? Used for policies like mine to improve quality with few unintended consequences?	Do I know what actions I must take to improve my health? Used by patients like me to improve health with few unintended consequences?
When used as part of measure set, measures are:	Represents multiple conditions, settings of care, populations, types of data (survey, administrative data, medical records), types of measures (structure, process, outcomes), and perspectives (patient, provider, system, society) as appropriate?		
Balanced Able to be disaggregated	Identifies individual measures that can be improved?		

and population health. Also related are the National Guidelines Clearinghouse (http://www.guideline.gov) and the Health Care Innovations Exchange (http://www.innovations.ahrq.gov), collections of clinical guidelines and descriptions of successful uses of measures, respectively.

Potential users should examine the attributes of specific measures to ensure that they are appropriate for their intended application (Table 9-3) and can measure change reliably and validly.[6] A number of organizations have developed scales or rating systems that summarize performance across multiple dimensions. Sometimes referred to as composite measures (e.g., a letter grade from the Leapfrog Group for hospital safety), these scales vary in comprehensiveness with little consensus regarding how components of a summary scale should be weighted. Indeed, it is not uncommon for a hospital to receive an "F" from one group and be rated a "top performer" by another. Thus, although appealing in their simplicity, the optimal use of these approaches remains unresolved.

MEASURING HEALTH AND HEALTH CARE AS PARTS OF A SYSTEM

Measuring health and health care together is also important for understanding the system as a whole. Patients, providers, and policymakers generally agree that the paramount goal of the health system is to improve health. At the population health level, however, factors other than medical care are highly influential. For example, population health is affected as much by health behaviors—such as diet, physical activity, smoking, and alcohol and drug use—as by the direct provision of medical care. Social characteristics (e.g., poverty, education, crime, and residential segregation) and physical determinants (e.g., housing and the natural and built environment) also impact population health to a greater extent than medical care (Chapter 4). Discrimination and bias have adverse effects on population health, including structural racism in social policies, such as housing and education, and algorithmic biases in clinical decision-support tools that may advantage some groups over others.[7] These issues must be addressed locally and systematically to enable all patients to derive maximal benefit from medical care and to achieve health equity. Explicitly measuring and rewarding equitable care is one component of achieving excellent care for all patients.[8,9]

Viewing medical care as a component of a system for generating and preserving population health has many implications for physicians and other health care providers. First, it emphasizes the importance of services to encourage healthy lifestyles and prevent the development of disease. For example, efforts to prevent tobacco use (Chapter 363) among adolescents (Chapter 21) may yield greater population health benefits than treating the complications of nicotine addiction later in life. Second, it serves as a reminder that patients who seek care have widely varying attributes and resources, factors that may affect their ability to comply with treatment recommendations. As a consequence, it may be important to consider medications with lower out-of-pocket costs for low-income patients and to simplify instructions to a patient's level of health literacy. Third, it recognizes how environmental factors outside of the control of physicians often have a large impact on population health. When health care measures are used to assess quality, adjustment for these factors is critical to ensure that comparisons are not biased. Fourth, it stresses the need for a culturally competent, diverse, and inclusive provider workforce. For example, in a randomized controlled trial, Black men were more likely to opt for indicated preventive services after consultation with a Black male doctor than with a non-Black male doctor.[10]

The SARS-CoV-2 pandemic has emphasized the relevance of telehealth for quality of care,[11] especially for a geographically dispersed population. However, telehealth also has the potential to worsen disparities because of differential access to and comfort with suitable devices.[12] In the Department of Veterans Affairs health care system, for example, explicit attention to the digital divide enabled rapid substitution of virtual care for in-clinic care with few disparities so that veterans with lower income, higher disability, and more chronic conditions were equally likely to receive virtual care during the pandemic.[13]

Another virtue of measuring health and health care together is to assess the value of components of the health system or the health system as a whole. U.S. national health expenditures have increased over 100 times from $27 billion (5.0% of the gross domestic product) in 1960 to $3.2 trillion in 2015 (17.8% of the gross domestic product) (Fig. 9-1). They are projected to exceed $5.5 trillion in 2025 and account for 20% of the gross domestic product. Expenditures on hospital care, physician and clinical services, prescription drugs, and the administration of health insurance account for 70% of total national health expenditures. Payers and employers can examine the cost-effectiveness of specific services and promote those that yield the largest health benefits for each dollar spent. U.S. health care processes rank much higher than health outcomes, despite the world's highest health care expenditures. In the United States the differential between the world's highest per capita expenditures but only the 46th longest life expectancy is in part because social conditions, such as poverty and lack of health insurance, may prevent even excellent medical care from achieving the best health outcomes.[14]

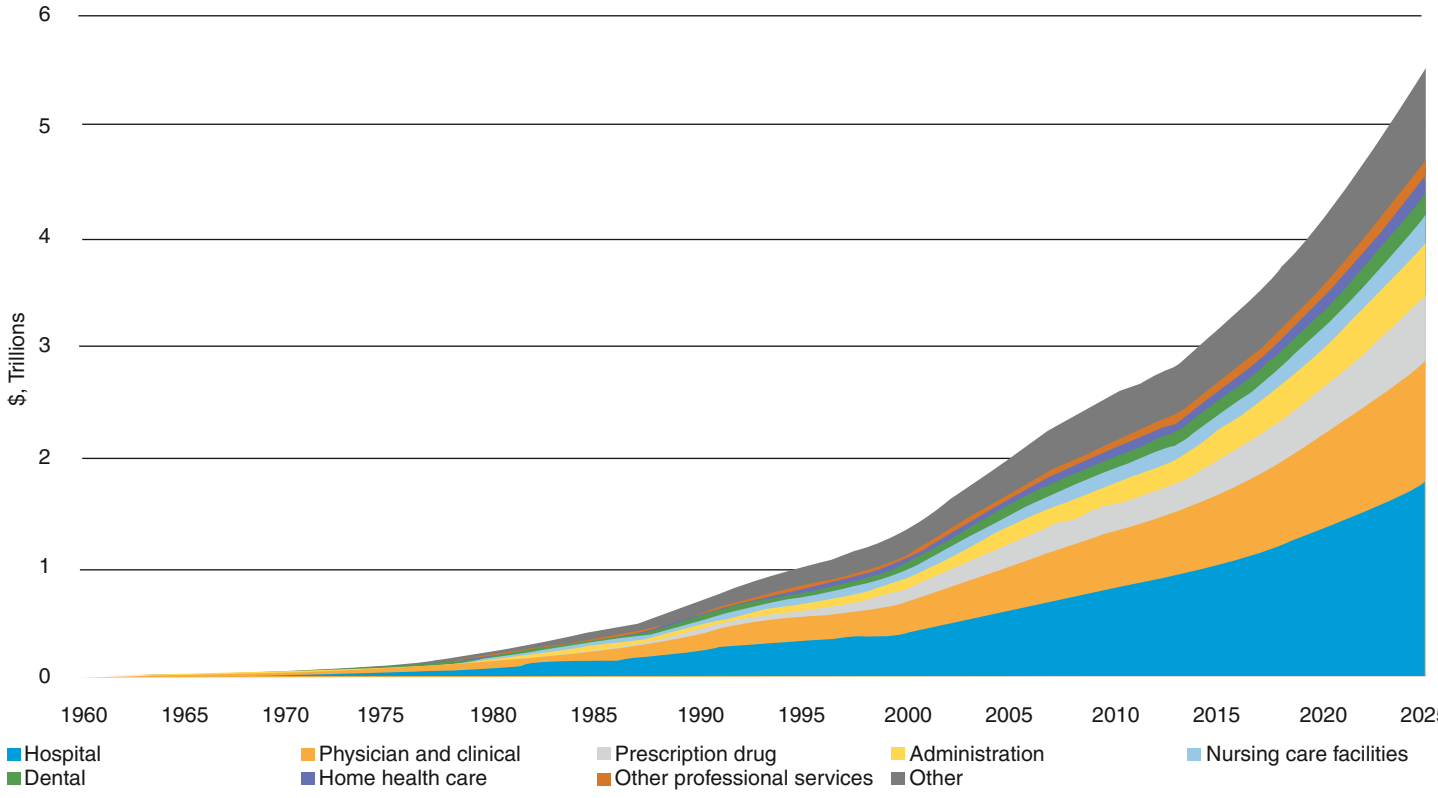

FIGURE 9-1. National health expenditures by select components, 1960-2025. Estimates for 1960-2015 are based on historical data; estimates for 2016-2025 are projections. Expenditures do not adjust for inflation. Administration includes health insurance expenditures other than health benefits paid as well as administration of government programs. (Source: CMS National Health Expenditure Data, https://www.cms.gov/Research-Statistics-Data-and-Systems/Statistics-Trends-and-Reports/NationalHealthExpendData/index.html. Accessed May 10, 2019.)

Physicians also have a critical role in ensuring that health resources are allocated wisely.[15] Unfortunately, about one third of U.S. health care expenditures probably do not improve health. As just one example, about 10% of patients in intensive care units are identified by critical care specialists as receiving clearly futile care. Physicians commonly overestimate the benefits and underestimate the harms of screening, tests, and treatments. As a result, unnecessary tests or procedures add to costs and can also increase morbidity or even mortality. Attempts to reduce such unnecessary and even harmful medical care must, of course, be balanced by being sure that potentially beneficial care is not reduced.

10 QUALITY, SAFETY, AND VALUE

ROBERT M. WACHTER AND KAVEH G. SHOJANIA

Scores of studies demonstrate that the quality and safety of modern health care leave much to be desired, despite the fact that most physicians are well trained and work very hard. Undeniable evidence clearly documents stunning variations in patterns of care that are neither supported by evidence nor justified by outcomes, major gaps between the scientific evidence and its application in clinical practice, and staggering numbers of serious medical errors. The recognition of these quality and safety problems has catalyzed major transformations in thinking and practice, with new technologies, regulations, training models, incentive systems, and more.

To appreciate the problem and address it requires an understanding of quality measurement and improvement, the safety of patients, and value, which is the confluence of safety, quality, and cost.

QUALITY

DEFINITION

The National Academy of Medicine has defined quality of care in terms of "the degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge." It also identified six distinct dimensions of quality (Table 10-1). Estimates that 44,000 to 98,000 Americans died each year from medical error—the equivalent of a jumbo jet crashing every day and a half—meant patient safety received most of the initial attention,[1] even if many of these preventable deaths may occur in very sick patients with less than a 3-month life expectancy. Attention to other dimensions of effectiveness, efficiency, and patient-centeredness has subsequently followed, with a significant subsequent decline in adverse inpatient events.[2] Nevertheless, adverse events are noted in about 25% of inpatient admissions, about one fourth of which are preventable,[3] and in about 2% of emergency department visits.[4] The lesser attention paid to equity over the past two decades has changed as a result of the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) pandemic and support for antiracism movements, both of which have highlighted long-standing disparities (Chapter 4) in health care and health outcomes by race and other socioeconomic factors.[5] The climate crisis (Chapter 17) also threatens to exacerbate existing disparities.

Historically, the lack of clinical evidence and the apprenticeship model of medical training promoted an idiosyncratic practice style by which a senior clinician or a marquee medical center determined the standard of care—a tradition now sometimes termed *eminence-based medicine*. Without discounting the value of experience and mature clinical judgment, the modern paradigm for determining optimal practice has changed, driven by the explosion in clinical research during the past 30 years. For example, the number of clinical trials registered on clinicaltrials.gov grew from about 2000 in the year 2000 to more than 360,000 in 2020. This research has helped define "best practices" in many areas of medicine, from preventive strategies for a healthy 62-year-old

ABSTRACT

The goal of medicine is to deliver care that is high quality, safe, timely, equitable, and patient-centered and to do so at the lowest possible cost. Studies over the past generation have demonstrated important gaps in all of these areas. In response to these gaps, increasing emphasis is being placed on implementing strategies—at both the individual clinician and the system level—to improve quality, safety, and health care value. Such strategies tend to emphasize a systems approach to improvement, teamwork, and learning from mistakes and quality gaps, in part by taking advantage of technology and tools such as electronic health records. The policy and payment environments also play important roles in creating appropriate accountabilities and incentives for both clinicians and health care systems to emphasize care improvement as a core activity and an imperative.

KEYWORDS

quality of care
patient safety

health care value
organization of care
outcomes
safety culture

TABLE 10-1 THE INSTITUTE OF MEDICINE'S SIX QUALITY AIMS

Patient safety	Avoiding harm from medical care
Patient centeredness	Providing care that respects and responds to an individual patient's preferences, needs, and values
Effectiveness	Providing evidence-based care
Efficiency	Avoiding waste
Timeliness	Reducing waits and harmful delays
Equity	Care that does not vary in quality because of gender, ethnicity, geographic location, or socioeconomic status

From Committee on Quality of Health Care in America, Institute of Medicine. *Crossing the Quality Chasm: A New Health System for the 21st Century*. Washington, DC: National Academy Press; 2001.

outpatient (Chapter 12) to the treatment of a patient with acute myocardial infarction and cardiogenic shock (Chapters 58 and 93).

The Donabedian triad, which divides quality measures into *structure* (how care is organized), *process* (what is done), and *outcomes* (what happens to the patient), remains the most popular construct for quality measurement. Each element of the triad has important advantages and disadvantages (Table 10-2). Many widely used quality indicators are process measures for which clinical research has established a link between such processes and improved outcomes. An example is the rate at which aspirin or a β-blocker is given to survivors of a myocardial infarction before hospital discharge (Chapter 58). However, when processes are less relevant and the science of case-mix adjustment is suitably advanced (e.g., cardiac bypass surgery; Chapter 59), outcome measurement (e.g., risk-adjusted mortality rate or 30-day readmission rate) is increasingly used. In other areas involving complex processes, structural measures are used as proxies for quality; examples here include the presence of intensivists to staff critical care units, a dedicated stroke service, and computerized physician order entry systems. Nevertheless, outcomes remain the key issue for patients and payers, so some experts advocate greater emphasis on outcome-based measurements.

THE EPIDEMIOLOGY OF QUALITY-RELATED PROBLEMS

It is now well established that there are large and clinically indefensible variations in care from one city or region to another. Furthermore, U.S. practice achieves guideline-based targets for controlling common chronic conditions, such as diabetes and hypertension, for only about 50% of patients.[6,7]

LEVERS FOR CHANGE

For physicians, policymakers, administrators, and patients, evidence of major problems with quality has led to the recognition of structural problems that prevent the delivery of the highest quality of care. These problems include the lack of information regarding the performance of a provider or institution, the absence of incentives for quality improvement, the challenge for practicing physicians to stay abreast of modern evidence-based medicine, and the absence of an information technology support system for quality.

The first step in quality improvement is the creation of practice standards against which to measure quality. Scores of such measures have been promulgated by a variety of organizations, including payers (such as the Centers for Medicare and Medicaid Services), accreditors (such as The Joint Commission), and medical societies. These measures have identified many opportunities for improvement among individual physicians, practices, and hospitals.

Given the volume of new literature published each year, individual physicians cannot keep up with all the evidence-based advances in their fields. *Practice guidelines*, such as those for the treatment of community-acquired pneumonia (Chapter 85) or the prophylaxis of deep venous thrombosis (Chapter 68), aim to synthesize evidence-based best practices into a set of summary recommendations. Although concerns about "cookbook medicine" linger, there is a growing consensus that best practices should be "hard wired" if possible. The major challenges are to update guidelines as new knowledge accumulates and to recognize the complexity of guidelines when patients have multiple, potentially overlapping illnesses. *Clinical pathways* are similar to guidelines but attempt to codify a series of steps, usually temporally (on day 1, do the following; on day 2, do the following; and so forth), making them more useful for stereotypical processes such as the postoperative management of patients after hip replacement. As more health care delivery organizations become computerized, pathways and guidelines are often translated into *order sets* or *clinical decision support systems* to guide clinicians at the point of care.

TABLE 10-2 COMPARISON OF THREE MEASURES OF CLINICAL QUALITY: THE DONABEDIAN TRIAD

MEASURE	SIMPLE DEFINITION	ADVANTAGES	DISADVANTAGES
Structure	How was care organized?	May be highly relevant in a complex health system	May fail to capture the quality of care by individual physicians Difficult to determine the "gold standard"
Process	What was done?	More easily measured and acted on than outcomes May not require case-mix adjustment No time lag—can be measured when care is provided May directly reflect quality (if carefully chosen)	A proxy for outcomes Not all may agree on "gold standard" processes May promote "cookbook" medicine, especially if physicians and health systems try to "game" their performance
Outcomes	What happened to the patient?	What we really care about	May take years to occur May reflect patient factors more than quality of care Requires case-mix and other adjustment to prevent "apples-to-oranges" comparisons

Modified from Donabedian A. The quality of care. How can it be assessed? *JAMA*. 1988;270:1743-1748; and Shojania KG, Showstack J, Wachter R. Assessing hospital quality: a review for clinicians. *Eff Clin Pract*. 2001;4:82-90.

Although professionalism (Chapter 1) should be a sufficient incentive for physicians to provide high-quality care, physicians are only human. Momentary lapses in attention can lead to forgetting to check for allergies before prescribing medications or ensuring a new inpatient's order is entered into the correct patient's record. Emotions can also play a role. Disruptive patients may induce doctors to make more errors,[A1] and rudeness from colleagues can degrade the performance of entire teams.

As a result, the reliable delivery of high-quality care depends on creating systems and organizational cultures that reduce predictable problems in human performance. Such systems require significant investments in educating physicians, hiring case managers or clinical pharmacists, building digital capacity, and developing guidelines. The historical payment model in the United States, which compensates physicians and hospitals on the basis of volume rather than quality, provides no incentive to make the requisite investments, but this situation is changing.

THE CHANGING ENVIRONMENT FOR QUALITY

The recognition of major gaps in quality and of the need for systemic change to improve quality has led to a variety of initiatives to catalyze improvements. Virtually all involve several steps: defining reasonable quality measures (evidence-based measures; capturing appropriate structures, process, or outcomes), measuring the performance of providers or systems, and using these results to promote change. This final imperative creates the greatest degree of uncertainty and experimentation.

Although one might hope that simply giving a physician information about prior performance would generate meaningful improvement, this strategy yields only modest change at best. Increasingly, a more aggressive and transparent strategy, such as disseminating the results of quality measurement to key stakeholders, is being adopted. In some cases, simple transparency is the main strategy—the rationale being that providers will find the exposure of their gaps in quality to be sufficiently concerning or embarrassing to motivate improvement. Although there is little evidence that patients use such data to choose among physicians or hospitals, transparency itself has frequently resulted in impressive improvements in some publicly reported quality measures.

Some health systems have tried to improve quality by linking payments to achieving specific performance targets (pay for performance, or P4P). These P4P programs have produced surprisingly modest gains beyond the improvements achieved by simple transparency.[8] P4P also raises a host of concerns, including whether presently captured quality data are accurate,

whether payments should go to the best performers or those with the greatest improvements, whether existing measures adequately measure quality in patients with complex diseases, and whether P4P will create undue focus on certain measurable practices, leading to relative inattention to other important processes that are not being compensated. Another concern is that an overemphasis on "extrinsic" motivation (i.e., bonus payments) can actually extinguish "intrinsic" motivation (i.e., professionalism). The loss of improvements after removal of performance payments reaffirms this concern.[9] One variation on the P4P theme is Medicare's "no pay for adverse events" program, in which hospital payments are withheld for certain "preventable" adverse events, such as injuries from falls or health care–associated infections. As with P4P more generally, the impact of such programs on quality and safety has been surprisingly modest.

QUALITY IMPROVEMENT STRATEGIES

Whether the motivation is professionalism, embarrassment, or economics, the next question is how actually to improve the quality of care. There is no simple answer; successful institutions and physicians have used a variety of strategies. In general, most use a variation of a "plan, do, study, act" cycle, recognizing that quality improvement activities must be carefully planned and implemented, that their impact needs to be measured, and that the results of these activities often fall short and require iterative refinement.

"Plan, do, study, act" cycles can also optimize "off-the-shelf" interventions, such as computerized decision support systems and performance report cards, in which performance data are fed back to individual providers or teams ("audit and feedback").[A2] In some randomized trials, such interventions have shown dramatic improvements,[A3] but others have been disappointingly negative.[A4] As a result, meta-analyses of randomized trials evaluating these interventions over a range of quality measures show only small average gains in the percentages of patients who receive recommended care.[A5]

For quality improvement practices that require predictable repetition, efforts to "hard wire" the practice or to use alternative providers who focus on the activity are often beneficial. For example, the best strategy to increase the rate of pneumococcal vaccination (Chapter 15) among hospitalized patients with pneumonia is to embed it in a standard order set, either paper-based or computerized. Another example: having a nurse remove patients' shoes before the physician's entry can increase rates of diabetic foot examinations in an outpatient practice (Chapter 210). Now that the vast majority of hospitals and office practices have electronic health records, it has become easier to measure performance, to deliver real-time feedback to providers, and to "hard wire" evidence-based practices into clinicians' workflow.

Nevertheless, electronic health records also produce workflow problems of their own by generating as much as 5 hours of record keeping for every 8 hours of scheduled clinical time.[10] Electronic alerts are often inappropriate and can generate "alert fatigue" among clinicians.[11] More generally, a lesson of the last two decades is that improvement interventions can cause harms. In one noteworthy example, transition support and self-management tools for patients hospitalized with chronic obstructive pulmonary disease (COPD) were associated with significantly greater COPD-related hospitalizations and emergency department visits, without improvements in quality of life.[A6]

More complex and interdependent clinical situations pose even greater challenges for quality improvement. In these circumstances, bringing teams together to examine their practices and learn from each other can augment the applications of tools such as "plan, do, study, act" cycles. Many organizations have also adopted more sophisticated methodologies, such as Lean or Six Sigma, which involve mapping out all of the steps of a complex process (e.g., hospital discharge) in an attempt to reduce waste and imperfections in care. For a hospital or outpatient practice, the precise methodology chosen is probably less important than the decision to adopt a systematic approach to analyze complex processes and to identify potential opportunities for improvement.

PATIENT SAFETY

EPIDEMIOLOGY

The definition of quality includes safety, but it is sometimes important to emphasize safety per se. The millennia-old concept of "first, do no harm" further adds to the justification for giving special attention to safety.

This age-old interest in avoiding harm historically manifested itself in the form of periodic forums, such as morbidity and mortality conferences, to discuss errors. Now, however, there is a recognition of the need to teach about the nature of medical mistakes, invest in safety research, regulate safety standards, and emphasize safety improvements.

This emphasis is driven by a startling reality: 5 to 10% of hospitalized patients and 2 to 3% of ambulatory patients suffer preventable harm from their medical care.[12] These harms can result from medication errors, gaps in the discharge process, communication problems in intensive care units, or retained sponges in surgical patients—in short, virtually every aspect of modern medical care. Moreover, detailed clinical and statistical evidence of suboptimal safety has been reinforced by several high-profile and disquieting errors, sometimes apparently related to inadequate supervision and prolonged duty hours of trainees. These errors include the wrong patient undergoing a major procedure, the wrong limb being operated on, chemotherapy overdoses, mistaken mastectomies, and more. In the past few years, new classes of errors have emerged because of poorly designed health care information systems. In addition, increasing attention is focusing on areas that were previously underemphasized, such as diagnostic errors. Of note is that about 1% of all physicians account for 32% of malpractice claims paid nationally.

Because patients may be harmed despite receiving perfect care (i.e., from an accepted complication of surgery or a side effect of medication), it is important to separate *adverse events* from *errors*. The patient safety literature commonly defines an error as "an act or omission that leads to an unanticipated, undesirable outcome or to substantial potential for such an outcome." Adverse events, in contrast, are injuries due to medical management rather than the patient's underlying illness. This distinction is crucial. For example, when a patient who was appropriately prescribed vancomycin for a serious methicillin-resistant staphylococcal infection develops kidney injury despite a therapeutic serum level, an adverse event, not a medical error, has occurred. Conversely, if the serum level of antibiotic was supratherapeutic because the patient had simultaneously been given other nephrotoxic agents, then a medical error would have occurred.

THE MODERN APPROACH TO PATIENT SAFETY

The historical approach to medical errors often has been to blame the clinician who was most proximate: whoever performed the surgery, hung the intravenous medication, or mixed the chemotherapy. It is now recognized that this approach fails to appreciate that most errors are committed by hardworking, well-trained individuals, and such errors are unlikely to be prevented by admonishing people to be more careful or by shaming and suing them. Instead, the modern approach, known as *systems thinking*, holds that humans will inevitably err and that safety depends on creating systems that anticipate errors and either prevent or catch them before they cause harm. Such an approach has been the cornerstone of safety improvements in other high-risk industries for some time.

The "Swiss cheese" model of accidents, drawn from innumerable investigations of accidents in commercial aviation and the nuclear power industry, for example, emphasizes that single errors by one individual working in an otherwise safety-conscious system rarely cause harm. Instead, such errors must penetrate multiple incomplete layers of protection ("layers of Swiss cheese") to cause terrible harm. The lesson is to focus not on the futile goal of trying to perfect human behavior, but rather on creating multiple overlapping layers of protection to decrease the probability that the holes in the Swiss cheese will ever align, allowing an error to slip through.

HOW TO IMPROVE PATIENT SAFETY

Drawing on these models, modern thinking emphasizes efforts to design and implement systems to prevent or catch errors. For example, errors in routine behaviors can best be prevented by building in redundancies and crosschecks in the form of checklists, read-backs, and other standardized safety procedures, such as counting sponges in the operating room, signing a surgical site before an operation, or asking patients their names before administering a medication. The use of checklists for the placement of central lines and to prepare patients for surgery has produced some remarkable reductions in morbidity and mortality. Yet even this obvious intervention has shown inconsistent benefit across studies.[13,14]

One way to decrease errors at the person-machine interface is by the use of "forcing functions," engineering solutions that decrease the probability of human error. The classic example outside of medicine is the modification of automobile braking systems to make it impossible to place a car in reverse when the driver's foot is off the brake. In health care, forcing functions include changing the gas nozzles and connectors so that anesthesiologists cannot mistakenly hook up the wrong gas (such as nitrogen instead of oxygen) and administer it to a patient. Given the ever-increasing complexity of modern medicine, building in such forcing functions in intravenous pumps, defibrillators, mechanical ventilators, and computerized order entry systems will be crucial to safety.

In addition to better systems, communication and teamwork must be improved. All commercial pilots must take "crew resource management" courses, in which they train for emergencies with other crew members, learn to flatten hierarchies that might stifle open communication, communicate clearly with standard language, and use checklists and other systematic approaches. The evidence that such interventions in medical care will improve the safety of patients is persuasive.[15] The goal is a "culture of safety"—an environment in which teamwork, clear communication, and openness about errors, both with other health care professionals and with patients, is the norm.

Another key principle in ensuring the safety of patients is to learn from one's mistakes. Safe systems have a culture in which errors are openly discussed, often in morbidity and mortality conferences. To be most useful, these discussions should be interdisciplinary (involving physicians and other health professionals), identify when the errors occurred, and emphasize systems thinking and solutions; they should not be punitive. In addition to open discussions during conferences, safe organizations build in mechanisms to hear about errors from frontline staff, often through "incident reporting systems"; they also perform detailed "root cause" analyses of major errors or "sentinel events" in an effort to define all the layers of Swiss cheese that need improvement. The importance of open communication extends to patients as well. Disclosure of errors is now required by The Joint Commission. Patients and families value such openness, and reasonably strong evidence indicates that disclosure of errors might decrease the chance of a malpractice suit.

Finally, there is increasing appreciation of the importance of a well-trained, well-staffed, well-rested, and experienced[16] work force for the delivery of safe care. Lower nurse-to-patient ratios,[17] lack of residents, low procedural volumes, and lack of board certification are all linked to poor outcomes for patients. Safer systems cannot be created if the providers are overextended or poorly trained or supervised. In the United States, the Accreditation Council for Graduate Medical Education has limited duty hours for residents and has prohibited first-year residents from working 24-hour shifts. Evidence to date confirms that these standards have improved residents' quality of life but not patient safety, probably because of the concomitant increase in risky handoffs (in fact, the ban on 24-hour shifts was lifted in 2017 based on such studies).[A7,A8]

In the absence of comparative evidence and in light of the high cost of interventions such as improved staffing, computerized order entry, and teamwork training, even institutions committed to safety must often make difficult choices. For example, medication reconciliation represents a widely promoted patient safety intervention. The typical version generates small reductions in unintentional medication changes and unclear reductions in actual harm.[18] By contrast, a more intensive version, involving ongoing involvement from clinical pharmacists after hospital discharge, can improve patient outcomes and reduce visits to the hospital.[A9] Given the natural tendency to focus on practices that are measured, publicly reported, and compensated, institutions and physicians tend to focus first on areas that are subject to regulation or on initiatives with multiple potential benefits, such as computerization. For example, computerization was promoted in the United States by a federal incentive program, which between 2010 and 2015 provided billions of dollars to hospitals and physicians that implemented computer systems meeting certain "Meaningful Use" standards. Today, more than 90% of U.S. hospitals and 80% of office practices use electronic health records, with some evidence of improved safety as a result.

Because improving culture is difficult to measure and to regulate, there is concern that it will not be as high a priority as it should be. Moreover, a safe culture depends on balancing the imperative to improve systems with the need to define and enforce accountability. The safety field is increasingly emphasizing more active enforcement of policies that address problems such as disruptive behavior by clinicians and failure to adhere to evidence-based safety practices. Organizations that are particularly adept at recovering from mistakes and ensuring safety have been called "high reliability" organizations. The term "learning health system" is used to refer to organizations that iteratively learn from both successes and failures.

QUALITY AND SAFETY DURING A PANDEMIC

The coronavirus disease 2019 (COVID-19) pandemic (Chapters 335 to 337) created enormous stresses on health care and public health systems, and it also raised important issues regarding quality and safety. First, the pandemic had disproportionate impacts on communities of color and on older individuals,[19] particularly people living in congregate care facilities. Although some of these health care disparities may have been explained by different levels of exposure to the virus, they may also reflect disparities in the quality and safety of care for these communities and in these settings (Chapter 4). In geographic areas that experienced rapid surges in cases, quality and safety were undoubtedly compromised by an overwhelmed health care system, most likely mediated by availability of resources, such as staff and hospital beds.[20] In addition, the pandemic led to a sharp rise in the use of telemedicine, and with it came considerable debate about the quality and safety of virtual care.[21] This latter topic will remain a key issue as health care becomes increasingly digital.

VALUE: CONNECTING SAFETY AND QUALITY TO COST

Outside of health care, most purchasing decisions are based on perceived value: quality ÷ cost. Health care decisions historically have not been made this way, in part because of the limited ability of patients and payers to make rational judgments about the quality and safety of a given provider or system, and in part because health care insurance insulates patients from the full cost of care. In the United States, which spends nearly 20% of its Gross Domestic Product and about twice as much as other high-income countries on health care,[22] policy pressures are increasingly being brought to bear on the entire value equation, that is, promoting value, not volume. Such initiatives are especially timely given the consolidation of U.S. hospital systems by mergers and acquisitions that generally have mixed impacts on the quality of care and the patient experience.[23] For example, Medicare's Value-based Purchasing program modifies hospital reimbursement on the basis of quality, safety, and patient satisfaction scores. The organization's readmission initiative threatens substantial cuts in reimbursement to hospitals with higher-than-expected 30-day readmission rates. Other federal programs seek to drive physicians and hospitals into arrangements in which they accept a fixed payment to manage a population of patients (Accountable Care Organizations) or for an episode of illness (bundled payments). Although such programs are controversial and of variable success,[24] they reflect a growing focus on quality, safety, the patient's experience, and the costs of care. Interestingly, the care of Medicare patients at major teaching hospitals is associated with better outcomes without higher costs.[25]

Recent years have seen increased efforts to identify and eliminate low-value care—care that adds costs but no, or insufficient, benefit.[26] Many of the techniques described earlier (audit and feedback, "hard wiring" best practices, improving culture) are applicable to these efforts. Nevertheless, the fact that physicians and health care organizations may benefit financially from such care (such as in the case of unneeded procedures) or that patients may request it (such as in unnecessary antibiotics for viral infections) means that efforts to eliminate low-value care often take on a public, even political, dimension. Whether attempts to understand such overutilization[27] can offset these pressures nationally is currently unknown.

11 POPULATION HEALTH

KIRSTEN BIBBINS-DOMINGO

In addition to understanding the biology of health, the pathobiology of disease, and the principles of diagnosis and individual therapy, clinicians also must be familiar with the concept of population health. Population health can be defined as the health outcomes of a group of individuals, whether based on geography (Chapter 5), ethnicity or socioeconomic status (Chapter 4), age (Chapters 21 and 24), gender or gender identity (Chapter 214), or other attributes, such as employment (Chapter 16), disability, homelessness, or incarceration. The field of population health includes health outcomes, patterns of the determinants that influence health, and the policies and interventions that link these two.

Population health is also a priority for health care organizations. Improving the U.S. health care system requires simultaneous pursuit of three aims: improving the experience of care for patients, reducing per capita costs of health care, and improving the health of populations.[1] In this conceptualization, the improvement of population health is central to high-quality health care (Chapter 10), potentially augmented by changing health care financing toward rewarding value over volume and specifically incentivizing improvements in population-based outcomes. These changes in payment models have led to the creation of an infrastructure that is often referred to as "population health management."

POPULATION HEALTH MANAGEMENT

Population health management describes how a health care organization that is interested in quality, value, and improvements in population health can deploy its resources to address areas of need within a population. Population health management strategies focus not only on the care that is provided to an individual during an outpatient visit or hospitalization but also on managing the health of all patients with a particular condition as well as the entire population for which an organization has responsibility. The scope of these strategies generally includes expanded preventive services, care models that detect and intercede when early signs of health deterioration are identified, and community-based programs that address care for complex conditions outside of clinical settings, including the social issues that often complicate the management of chronic conditions.

Data suggest that population health management strategies can improve health outcomes. For example, consider the delivery of a preventive intervention such as evidence-based cancer screening to an entire population for which a health care organization has responsibility. When fecal immunochemical tests are directly mailed to all patients in a health care system, rates of screening for colon cancer increase. To be effective, however, such screening must be accompanied by rigorous plans for evaluating individuals who have a positive test result.[A1] Identifying all patients with a particular risk profile (e.g., obesity [Chapter 201] or pre-diabetes [Chapter 210]) may allow for more efficient enrollment of such patients into preventive care interventions (e.g., a diabetes prevention program). A population health management program can achieve 80 to 90% control rates for hypertension (Chapter 64) in an integrated health delivery system by focusing on structured treatment algorithms, team-based care, and an active management of hypertension registries. Online digital tools and telemedicine may allow for effective management of chronic conditions such as asthma,[A2] obesity,[A3] or diabetes.

Inherent in many population health management care models is the importance of team-based care that includes nonphysicians (e.g., nurses, nurse practitioners, pharmacists, and social workers, among others). Health care workers who work outside traditional clinical settings may be particularly important. For example, community health workers, who are trained to have basic knowledge of clinical conditions, can provide health coaching and psychosocial support, augment patient engagement by strengthening connections to outpatient care, facilitate navigation during transitions in care (e.g., from inpatient to outpatient or from primary care to specialty care), and identify relevant resources to address unmet social needs (e.g., food, housing, transportation). Outpatient models that include community health workers in the care of patients with multiple chronic conditions (e.g., diabetes, obesity, tobacco dependence, and hypertension) can improve control of these chronic conditions, improve mental health outcomes, improve quality of care, and decrease subsequent hospitalizations.[A4,A5] Similar approaches for high-risk patients at the time of hospital discharge demonstrate improvements in access to primary care and reductions in recurrent readmissions. Community health workers also have shown promise for mental health conditions such as depression (Chapter 362)[2] and geriatric conditions such as hearing loss.[A6] Economic analyses show positive returns on investment for models of care that incorporate community health workers,[3] but more widespread adoption has been limited by variability in the health care reimbursement, variability in training and licensing, and limited studies on the standardization of such interventions.[A7]

BEYOND POPULATION HEALTH MANAGEMENT TO POPULATION HEALTH

Population health management is being incorporated into traditional health systems that are seeking to improve clinical prevention, management of chronic disease, value, and quality. However, inherent in the broader concept of population health is the recognition that clinical care accounts only for about 20% of the factors responsible for health outcomes. Even after also accounting for individual behaviors that might be addressed in the health care setting, other factors (often referred to as the social determinants of health) account for far more (Fig. 11-1). These social drivers of health pose specific challenges for the delivery of health care. Patients at highest risk for poor clinical outcomes often have the highest degree of need with respect to these social drivers of health, and individual clinicians often feel ill-equipped to address these needs. The systemic nature of many social drivers of health are best addressed with broader policies and programs that are widely available to groups of individuals with similar needs rather than by simply addressing the unmet needs of an individual patient at one point in time.[4] This recognition has led to an increased interest in how physicians and health systems might move beyond targeted population health management programs to address social and structural determinants of health more directly.

Interventions focused on the social determinants of health or addressing social needs of patients in health care settings have had variable success. Increasing attention is focusing on screening all patients for social needs, with the goal of addressing any unmet needs,[A8] but interventions to address food insecurity, financial strain, and housing instability have not yet resulted in replicable approaches to guide their widespread implementation.[5] For example, a trial of providing rideshare transportation to patients with transportation needs failed to improve attendance at outpatient visits,[A9] suggesting that addressing a single determinant of health may be insufficient in patients who may also have multiple additional needs (e.g., economic, food, shelter). Providing permanent supportive housing for chronically homeless individuals who are high users of health care services can increase outpatient follow-up for mental health, decrease emergency psychiatric visits, and decrease the use of homeless shelters, but not reduce overall emergency department visits or hospitalizations.[A10] Sustainable models for addressing social needs such as housing within the context of health care delivery generally require partnerships with institutions for whom housing is their primary focus. Similarly, data on addressing food insecurity for diabetic patients in health care settings support the use of partnerships with food pantries.[A11] However, the difficulties of addressing complex social needs in high-risk patients is exemplified by the failure of an intervention based on a team of nurses, social workers, and community health workers to reduce hospital readmissions among high users of health care with medically and socially complex problems,[A12] despite high engagement of patients with the program.

Although the importance of addressing the social drivers of health is critical for improving population health, the most effective means for addressing such challenges within the context of health care delivery remains uncertain. However, data suggest five types of interventions are most likely to address social needs and thereby improve individual and population health (Fig. 11-2). All clinicians and health care organizations should be *aware* of the social determinants of health and the potential needs and assets of patients with respect to these social factors. In the context of health care delivery, clinical teams may identify and address the social needs of an individual patient by providing direct *assistance* (e.g., providing a voucher for transportation or referral to a food assistance program). *Adjustments* to clinical care may also be appropriate to minimize the burden of social need (e.g., telehealth visits for patients with transportation needs or a lower-cost diagnostic evaluation or treatment regimen for patients with limited resources). Since addressing social needs one patient at a time may not be effective or cost-effective, changes in structural factors that result in social needs for larger populations of patients are usually better addressed by *alignment* with other sectors (e.g., partnerships with housing agencies and social services to develop programs for permanent supportive housing following hospitalization) or joint *advocacy* for changes in housing policies.

ABSTRACT

Population health refers to the health outcomes of groups of individuals, where the group may be defined by geography, age, ethnicity, socioeconomic status, or other attributes. The field of population health includes not only the study of the health outcomes for populations, but also the patterns of determinants that influence these outcomes, as well as the policies and interventions that link the two. Clinicians must have an understanding of population health, particularly how social and structural determinants of health may impact their patients' health and the optimal provision of individualized health care. Population health has also become a priority of U.S. health systems and has motivated the creation of infrastructure referred to as population health management and often including expanded preventive services, team-based care models that detect and intercede on early signs of health deterioration, and community-based programs that address care of complex conditions outside of traditional clinical care settings. Emerging evidence supports that such programs improve health outcomes for individual patients, particularly related to the prevention and the care of chronic conditions.

12 THE PREVENTIVE HEALTH VISIT

MARY B. BARTON AND TRACY A. WOLFF

A general health check-up for adults has not been proven to reduce mortality, but it is associated with better recognition and treatment of chronic diseases as well as better patient-reported outcomes.[1] The value of the periodic health visit is increased by a focus on primary and secondary prevention. The appropriate preventive services, including screening and lifestyle counseling, as well as their frequency, vary with the age, sex, and individual risk factors of each patient.

The U.S. Preventive Services Task Force (USPSTF) recommendations are used by major primary care groups, many health plans, and quality organizations, and their A and B recommendations guide preventive services that are covered under the Affordable Care Act. The USPSTF bases its recommendations on two factors: an estimate of the *net benefits* (benefits minus harms) of a service and an assessment of the *certainty* of that estimate, based on the rigor of supporting studies. Grade A recommendations require high certainty of a substantial net benefit, most often from large, prospective, controlled studies that measure morbidity or mortality.[2] Grade B recommendations have at least moderate certainty of at least a moderate benefit. USPSTF recommendations are thus more conservative than those of some subspecialty organizations that may give more weight to indirect evidence, such as earlier detection of disease, and less weight to potential harms of interventions. Clinicians can draw several general conclusions from an evidence-based approach to prevention: we should be selective in our use of screening tests, especially in older patients, and involve patients in decisions about specific services for which a small chance of benefit must be balanced against possible harm.

HISTORY AND RISK ASSESSMENT

The history and risk assessment are important tools to identify individuals who may need additional screening tests or immunizations not generally recommended for their age group or who may benefit from specific counseling to promote healthy behaviors. Formal health risk appraisals should be linked to a system to provide specific feedback and targeted interventions. Risk assessment should address the following:

- Use of tobacco, alcohol, and other drugs (especially injection drugs) (Chapters 363, 364, and 365)
- Diet (Chapters 13 and 201)
- Physical activity (Chapter 14)
- Sexual behavior that may increase the risk for sexually transmitted diseases or unintended pregnancy (Chapters 264, 353, and 356)
- Family history of cancer and heart disease
- Birthplace and current residence (community risk for infectious diseases)
- Presence of chronic diseases, such as diabetes, and of other cardiovascular risk factors
- Presence of social risk factors, such as housing instability, food insecurity, financial strain

SCREENING FOR EARLY DISEASE OR ASYMPTOMATIC RISK FACTORS

Every year, new screening tests are introduced and marketed on the basis of their ability to detect unrecognized diseases or risk factors for disease. Other conditions need to be fulfilled for a screening test to be worthwhile for routine use, however (Table 12-1). Benefits of screening must be balanced against the potential harms, including false-positive results and the risks and costs of follow-up procedures or treatments. Even when tests have high specificity, the majority of positive results will be false-positive results if the test is used to screen healthy populations for uncommon conditions such as cancer (Chapter 8). There is evidence that cancer screening can lead to "overdiagnosis"—detection of slow-growing cancers that would never have caused clinical symptoms in a patient's lifetime. Overdiagnosis subjects patients to the side effects of treatment with no benefits. A relatively small number of screening tests have been proved beneficial for the general population (Table 12-2), but several screening tests are indicated for specific populations at risk (Table 12-3). Many commonly used screening tests are not recommended by the USPSTF (Table 12-4) because they provide little benefit or lack sufficient evidence to prove

TABLE 12-1 REQUIREMENTS OF AN EFFECTIVE SCREENING TEST

The disease being screened for is an important cause of morbidity and mortality.
Screening can detect disease in an early, asymptomatic phase.
Screening and treatment of patients with early disease or risk factors produce better health outcomes than does treatment of patients when they present with symptoms.
Screening test is acceptable to patients and clinicians—safe, convenient, acceptable false-positive rate, acceptable costs.
Benefits of early detection and asymptomatic treatment are sufficient to justify potential harms and costs of screening.

TABLE 12-2 PREVENTION RECOMMENDATIONS FOR THE GENERAL POPULATION: FROM THE U.S. PREVENTIVE SERVICES TASK FORCE AND OTHER SOURCES

SCREENING
Height, weight, and body mass index (BMI) calculation: periodically
Blood pressure: at least every 2 yr
Screen for alcohol misuse
Screen for unhealthy drug use
Brief screen for depression*
Total blood cholesterol, LDL, and HDL cholesterol: every 5 yr for men and women ≥20 yr with CHD risk factors and men ≥35 yr without CHD risk factors
Colorectal cancer screening: age 45-75 yr
Mammogram: at least every 2 yr for women 50-74 yr
Cervical cancer: Papanicolaou (Pap) test every 3 yr for women aged 21-29 yr; for women aged 30-65 yr, either Pap test every 3 yr or human papillomavirus (HPV) test with or without Pap every 5 yr
HIV test: at least once in all adults; repeat based on high-risk sexual activity
Hepatitis C screening at least once for persons ages 18 to 79 years, repeat based on continued risk
Chlamydia and gonorrhea: sexually active women ≤24 yr and older women at risk
Screening for bacteriuria in pregnant persons
Bone mineral density test: women ≥65 yr and high-risk women <65 yr
COUNSELING
Substance use
Tobacco cessation
Reduction of risky or harmful alcohol use
Diet and exercise
Limit saturated fat; maintain calorie balance; emphasize grains, fruits, and vegetables†
Regular physical activity
Sexual behavior
Unintended pregnancy: contraception
Interventions during pregnancy and after birth to support breastfeeding
Dental health: floss, brush with fluoride toothpaste daily
IMMUNIZATIONS
Pneumococcal vaccine (two preparations, administered 1 yr apart, age ≥65 yr)
Influenza vaccine (annual)
Tetanus-diphtheria (Td) boosters (every 10 yr)
Measles, mumps, rubella (MMR) vaccine (susceptible adults aged 19-49 yr)‡
Varicella (two doses, susceptible adults born after 1980)‡
Herpes zoster vaccine, two doses after age 50 yr
HPV vaccine (two doses, boys and girls ages 12-13 yr; three doses if given at ages 15-26 yr)
COVID-19 vaccine, with booster age >5 yr
PREVENTIVE MEDICATIONS
Multivitamin with folic acid (women planning or capable of pregnancy)

*Screening is most effective where adequate systems exist to ensure effective treatment and appropriate follow-up.

†Diet counseling is most effective when it targets at-risk groups (overweight or with CHD risk factors).

‡Immunity can be verified by serologic testing, documented history of illness, or vaccination.

CHD = coronary heart disease; COVID = coronavirus disease; HDL = high-density lipoprotein; HIV = human immunodeficiency virus; HPV = human papillomavirus; LDL = low-density lipoprotein.

USPSTF recommendations:

Sources: https://www.uspreventiveservicestaskforce.org/; other sources for Tables 12-2 and 12-3 include U.S. Department of Health and Human Services (diet, physical activity), Centers for Disease Control and Prevention (injury prevention, immunizations, dental health), and Health Resources and Services Administration (contraception).

ABSTRACT

Primary and secondary prevention is an essential part of primary care and the patient-centered medical home; the appropriate services and their frequency vary with the age, sex, and the risk factors of each individual patient. A preventive health visit should focus on screening tests with strong evidence of effectiveness; lifestyle counseling directed toward healthy diet, physical activity, and avoiding tobacco use and risky use of alcohol and other drugs; and discussion of possible preventive medications such as aspirin and statins. The most comprehensive prevention recommendations are produced by the U.S. Preventive Services Task Force (USPSTF). The USPSTF bases its recommendations on two factors: an estimate of the *net benefits* of a service and an assessment of the *certainty* of that estimate. Importantly, these recommendations apply to patients who do not have signs or symptoms of disease and who are at average risk for the particular disease that is the focus of the preventive intervention.

TABLE 12-3 RECOMMENDED SCREENING AND INTERVENTIONS FOR SELECTED POPULATIONS

POTENTIAL INTERVENTION	POPULATION
SCREENING	
Diabetes screen	Adults aged 35 to 70 yr with overweight or obesity
Ultrasound examination for abdominal aortic aneurysm	Males aged 65-75 yr with current or previous smoking history
Low-dose computed tomography for lung cancer	Adults with at least 20 pack-year smoking history (current adults who smoke, and those who quit smoking within past 15 years)
Syphilis (RPR/VDRL)	High-risk sexual behavior; consider local epidemiology*
Gonorrhea screen	High-risk sexual behavior; consider local epidemiology*
Tb screening	Persons who were born in, or are former residents of, high-risk countries, congregate settings, immunosuppressed
COUNSELING	
Exercise to prevent falls	Community dwelling adults ≥65 yr at increased risk for falls
Counseling to prevent STIs	Adults at increased risk
IMMUNIZATIONS	
Hepatitis B vaccine	Exposure to blood products; IV drug use; high-risk sexual behavior; travelers to high-risk areas
Hepatitis A vaccine	Persons living in or traveling to high-risk areas; institutionalized persons and workers in these institutions; those with certain chronic medical conditions
Meningococcal vaccine	First-year college students in dormitories; military recruits; those with asplenia; travelers to high-risk areas
Varicella vaccine	Adults born after 1980 without evidence of immunity
PREVENTIVE MEDICATIONS	
Statin	Adults over 40 yr at increased risk of cardiovascular disease
Breast cancer preventive medications	Women at increased risk for breast cancer and with low risk for thromboembolic complications
HIV preexposure prophylaxis	Adults at high risk of HIV acquisition

*Routine screening may be indicated in communities or settings where infection is prevalent.
HIV = human immunodeficiency virus; IV = intravenous; RPR = rapid plasma reagin; STI = sexually transmitted infection; Tb = tuberculosis; VDRL = Venereal Disease Research Laboratory.

TABLE 12-4 INTERVENTIONS NOT RECOMMENDED FOR ROUTINE USE IN ASYMPTOMATIC AVERAGE-RISK ADULTS*

PHYSICAL EXAMINATION
Oral examination for oral cancer (I)
Brief tests of mental status to detect dementia (I)
Vision and hearing tests in older adults (I)
Screening testicular examination (D)
BLOOD TEST
Routine blood tests for anemia
Blood level of C-reactive protein to predict coronary risk (I)
Blood tests for celiac disease (I)
Herpes serology (D)
Blood tests for ovarian cancer (D)
RADIOLOGY
Chest radiograph for lung cancer
Ultrasound examination for asymptomatic carotid artery stenosis (D)
Whole body computed tomographic scan
Ultrasound examination for ovarian cancer
Helical computed tomography for asymptomatic coronary disease (I)
OTHER
Resting or exercise electrocardiography (D) of asymptomatic coronary disease
Pulmonary function tests for chronic obstructive pulmonary disease (D)
Routine urine tests (for infection, cancer, or chronic kidney disease) (I)
Vitamin supplements (I, D)

*These services have either insufficient evidence to support routine use (I) or at least fair evidence that they provide no benefit or that harms outweigh benefits (D).

or disprove their value. Because only about 50% of U.S. adults see a primary care physician each year,[3] the responsibility for providing preventive services may increasingly fall to other clinicians.

DEPRESSION

Depression is common and frequently undetected in primary care (Chapter 362), and screening is specifically recommended in the adult general population, including pregnant and postpartum women. The most commonly used screen, and one of the simplest, is the Patient Health Questionnaire (PHQ)-9 (Table 12-5), which has nine items, each scored from 0 to 3. The PHQ-9 takes 5 to 10 minutes to administer.[4] A total score of 10 indicates moderate depression, whereas a score of 20 generally corresponds to severe depression. To improve outcomes, however, screening for depression must be linked to an organized system with staff support to ensure follow-up diagnostic assessment and treatment.

COGNITIVE IMPAIRMENT

By comparison, routine screening for cognitive impairment is more complicated. Despite excellent screening tools (Chapters 361 and 371),[5] no specific interventions have substantial impact on progression, so the USPSTF found insufficient evidence to support screening.[A1] Nevertheless, identification of cognitive impairment is included in Medicare's wellness visits and can guide family and other caregivers in ways that are likely to benefit the patient.

HIGH BLOOD PRESSURE, ABNORMAL LIPIDS, AND OTHER CARDIOVASCULAR RISK FACTORS

Overall cardiovascular disease (CVD) risk, based on age, sex, blood pressure, lipid levels, diabetes and smoking status, should be calculated at regular intervals to guide treatment decisions to reduce cardiovascular risk. Blood pressure should be measured at least every 2 years (Chapter 64), and home measurement[6] is recommended rather than beginning treatment based on an office measurement alone.[A2] The value of blood pressure screening in adolescents (Chapter 21) is less clear.[A3]

For lipids, the most commonly used risk estimation tool relies on measures of total cholesterol and high- and low-density lipoprotein cholesterol (Chapter 190) to estimate 10-year risk of coronary heart disease (http://tools.acc.org/ASCVD-Risk-Estimator). Statins are routinely recommended for patients who already have known atherosclerotic cardiovascular disease (Chapter 190). By comparison, the USPSTF, which focuses on primary prevention for individuals at risk for developing cardiovascular disease, recommends low- to moderate-dose statins for adults ages 40 to 75 years who have at least a 10% 10-year risk of CVD and at least one CVD risk factor.[A4] Recommendations from the American Heart Association and American College of Cardiology favor treatment for those with an estimated 10-year risk as low as 7.5%, whereas the USPSTF recommends individualizing treatment decisions for adults with a 10-year CVD risk of 7.5 to 10%.[7] The USPSTF concluded evidence was insufficient to recommend for or against beginning treatment after age 75 in adults with no evidence of CVD. Although factors such as C-reactive protein, homocysteine, and coronary calcification as assessed by computed tomography (CT) are associated with an increased risk for heart disease, the USPSTF has, at least so far, found insufficient evidence to recommend their routine use in risk assessment.

ABDOMINAL AORTIC ANEURYSM

Between 5 and 9% of men older than 65 years have an abdominal aortic aneurysm (Chapter 63). The risk for aneurysm is highest in smokers and is substantially lower in women (1%). The USPSTF recommends one-time screening with ultrasound examination in men aged 65 to 75 years who are current or former smokers,[8] based on trials demonstrating as much as a 40% lower death rate from abdominal aortic aneurysm rupture in screened men, even though it does not decrease all-cause mortality.[A5]

TABLE 12-5 PATIENT HEALTH QUESTIONNAIRE-9 (PHQ-9)

Over the last 2 weeks, how often have you been bothered by any of the following problems?

USE "✔" TO INDICATE YOUR ANSWER	NOT AT ALL	SEVERAL DAYS	MORE THAN HALF THE DAYS	NEARLY EVERY DAY
1. Little interest or pleasure in doing things	0	1	2	3
2. Feeling down, depressed, or hopeless	0	1	2	3
3. Trouble falling or staying asleep, or sleeping too much	0	1	2	3
4. Feeling tired or having little energy	0	1	2	3
5. Poor appetite or overeating	0	1	2	3
6. Feeling bad about yourself—or that you are a failure or have let yourself or your family down	0	1	2	3
7. Trouble concentrating on things, such as reading the newspaper or watching television	0	1	2	3
8. Moving or speaking so slowly that other people could have noticed. Or the opposite—being so fidgety or restless that you have been moving around a lot more than usual	0	1	2	3
9. Thoughts that you would be better off dead or of hurting yourself in some way	0	1	2	3
FOR OFFICE CODING	*0*	+___	+___	+___
		=Total Score:_____		

Developed by Drs. Robert L. Spitzer, Janet B.W. Williams, Kurt Kroenke, and colleagues.

COLORECTAL CANCER

Screening can reduce both the incidence of and mortality from colorectal cancer. Options for screening men and women older than 45 years include an annual highly sensitive fecal occult blood test (FOBT) or fecal immunochemical test, a multitargeted stool DNA test every 1 to 3 years, flexible sigmoidoscopy every 5 years (or every 10 years with annual FOBT), CT colonography every 5 years, or colonoscopy every 10 years (Chapter 179).[A6]

Colonoscopy combines detection with the opportunity for biopsy and removal of lesions, so it is preferred in some guidelines. It carries higher costs and risks, however, and no single strategy has proved to be more effective or cost-effective than the alternatives. The USPSTF recommends routine screening for adults ages 45 to 75 years and selective screening in adults ages 75 to 85 years.[9]

BREAST CANCER

In large trials, mammography screening (at intervals of 1 to 2 years, with or without clinical breast examination) reduces breast cancer mortality by 15 to 30% (Chapter 183). Most trials suggest that the benefits of screening extend to women in their 40s, but the benefits are smaller and the risks for false-positive results are higher than in women aged 50 to 70 years. If a woman aged 40 to 49 years has a two-fold increased risk for breast cancer compared with the average in her age group, she will have a similar benefit-to-harm ratio for biennial screening mammography as an average-risk woman aged 50 to 74 years. No studies provide data on the benefits of screening women aged 75 and older. In a collaborative study, six independent models predicted that an average of 80% of the benefit of mammography could be achieved with biennial rather than annual mammography, whereas national mammography surveillance data indicate that false-positive results and other harms of screening would be reduced by about half if women were screened every other year instead of yearly. The USPSTF recommends biennial screening mammography for women aged 50 to 74 years, that the decision to start screening mammography in women before age 50 years should be an individual decision, and that the current evidence is insufficient to assess the balance of benefits and harms of screening mammography in women aged 75 years or older.

Although many cancers are discovered by patients, teaching women to perform breast self-examination increases the likelihood that a woman will undergo further evaluation for an unimportant finding, but it does not improve outcomes. Widespread screening for *BRCA1* or *BRCA2*, inherited mutations that increase the risk for breast cancer, is not recommended, but the USPSTF recommends that primary care providers assess risk in women who have family members with breast, ovarian, tubal, or peritoneal cancer by using one of several family history risk assessment tools designed to identify women at risk for potentially harmful mutations. Women with a positive result on risk assessment should be referred for genetic counseling.[10]

CERVICAL CANCER

Papanicolaou (Pap) screening is highly effective in preventing invasive cervical cancer, but many women in the United States are screened more often than needed. The USPSTF and a multispecialty-society collaborative endorse starting screening at age 21 years and then screening women aged 21 to 30 years every 3 years, regardless of their sexual history or HPV vaccination status (Chapter 184). In women ages 30 to 65 years, the USPSTF recommends either Pap testing every 3 years or human papillomavirus (HPV) testing with or without Pap testing every 5 years[11] (Chapters 15 and 344).[A7] Aside from its value for performing a Pap test, evidence is inadequate for recommending a pelvic examination in asymptomatic, nonpregnant women. Women who have adequate screening histories and who are not otherwise at high risk should discontinue screening after 65 years of age. Screening is not indicated in women who have undergone a total hysterectomy for benign disease. Whether women who have received the HPV vaccine (Chapter 15) need different screening strategies is not yet known.

PROSTATE CANCER

Screening with prostate-specific antigen (PSA) can increase the detection of organ-confined prostate cancer, but three large trials provided conflicting results as to whether screening lowers morbidity or mortality from prostate cancer (Chapter 186). Based on long-term follow-up of those trials and studies of early treatment of screen-detected cancer,[A8] the USPSTF concluded that PSA-based screening programs in men ages 55 to 69 years may prevent up to 1 to 2 deaths from prostate cancer and up to 3 cases of metastatic prostate cancer per 1000 men screened over 13 years.[A9] These benefits are offset by harms of screening, including an approximate 1% risk of hospitalization after biopsy. More importantly, an estimated 20 to 50% of screen-detected cancers are "overdiagnosed" (i.e., they may subject patients to risks of unnecessary treatment). Men undergoing prostatectomy have 1 in 8 chance of developing long-term urinary incontinence, and 1 in 3 men experience long-term sexual impotence. More than 1 in 7 men who have radiation therapy experience long-term erectile dysfunction, and up to 30% or so of men experience long-term bothersome bowel symptoms, including bowel urgency and fecal incontinence. Because of the small benefit of screening with the PSA and potential harms of overdiagnosis and overtreatment, the USPSTF recommends individual decision making among men aged 55 to 69 years. The USPSTF recommends against PSA screening in men aged 70 years and older due to lack of benefits and increased harms.[12]

LUNG CANCER

The USPSTF recommends annual screening with low-dose CT in adults aged 50 to 80 years who have at least a 20 pack-year smoking history and who currently smoke or have quit within the last 15 years, based on trials that reported

relative reductions of death from lung cancer by 16 to 25% and of all-cause mortality by about 7%.[A10] The overall benefit of screening takes into account that individuals would have about two false positive CT scans over a lifetime of screening.[13] As many as 40% of screened persons will have another finding on CT, such as coronary artery calcification, a mass in the kidney or adrenal gland, or an aortic aneurysm.[14] These findings are of uncertain significance, but they may lead to additional procedures to evaluate them.

OSTEOPOROSIS

Tests of bone mineral density can identify men and women with a high risk for fracture as a result of osteoporosis and who may benefit from medications proved to lower the risk for fracture (Chapter 225). The USPSTF recommends screening for osteoporosis in women older than 65 years as well as in younger women who have risk factors that put them at comparable risk. The most widely used screening tool for the risk of hip fracture is bone mineral density of the hip assessed with dual-energy x-ray absorptiometry (DXA), although peripheral DXA and quantitative ultrasound are acceptable and have the advantage of portability. A tool developed by the World Health Organization (http://www.shef.ac.uk/FRAX/) incorporates bone mineral density and other risk factors, such as age and fracture history, to guide decisions.

THYROID DISEASE

Routine thyroid testing occasionally identifies patients with symptomatic but undiagnosed hypothyroidism (Chapter 207), but it more often detects subclinical hypothyroidism, which presents in 5% of women and 3% of men in the United States and is characterized by elevations in thyroid-stimulating hormone with normal levels of free thyroxine.

Because the benefits of treating subclinical hypothyroidism remain uncertain, the USPSTF does not recommend routine thyroid testing in the absence of symptoms. Clinicians should be alert to subtle signs of thyroid disease and have a low threshold for testing patients in high-risk groups, including postpartum and postmenopausal women.

DIABETES

Although the treatment of impaired fasting glucose or impaired glucose tolerance can delay progression to diabetes (Chapter 210), screening for type 2 diabetes does not improve mortality rates after 10 years of follow-up.[A11] Routine screening for diabetes beginning at age 45 years is recommended by some groups, but the USPSTF recommends screening for overweight or obese adults ages 35 to 70 years of age.[15] Clinicians should refer patients with abnormal blood glucose to intensive behavioral counseling interventions that can lower CVD risk. Although tight glucose control can reduce the incidence of microvascular disease, the benefit of early asymptomatic detection on clinically important retinopathy, neuropathy, and nephropathy is likely to be small.

HIV INFECTION

The USPSTF and Centers for Disease Control and Prevention (CDC) recommend screening for HIV infection (Chapters 356, 357, and 358) in all adolescents and adults aged 15 to 65 years,[16] including pregnant women.[17] Whether to continue screening after age 65 years depends upon risk factors such as new sexual partners. The optimal screening interval is unclear, but annual screening is reasonable in persons at very high risk, such as individuals who are actively engaged in risky sexual behaviors. Rescreening is not necessary in seronegative patients who have not been at increased risk since the last screen.

HEPATITIS B AND C INFECTIONS

Drugs for chronic hepatitis C and B infection (Chapter 135) have increased the ability to achieve viral suppression and prevent the complications of chronic liver disease in infected individuals.[A12] As a result, screening is recommended for hepatitis C in all adults ages 18 to 79 years, usually as just a one-time screen.[18] For hepatitis B, the evidence of a benefit is less clear,[A13] but screening is still recommended in adolescents and adults who are at increased risk of infection,[19] especially individuals born in countries with a high prevalence of hepatitis B or with a history of past or current injection drug use.

SEXUALLY TRANSMITTED DISEASE

Behavioral counseling is recommended to prevent sexually transmitted disease in sexually active adolescents and adults who are at increased risk.[A14,20] Screening for chlamydia and gonorrhea (Chapter 294) is recommended for all women aged 24 years and younger who are sexually active and for older women at risk.[A15,21] Nucleic acid amplification tests for chlamydia can be performed on cervical or urine specimens. Early detection of chlamydia can reduce pelvic inflammatory disease (Chapter 264), a risk factor for infertility and ectopic pregnancy. Similar benefits are likely from screening women for gonorrhea (Chapter 275). Women older than 25 years are at increased risk based on their current sexual behaviors and those of their partners. Syphilis testing is recommended in persons who are at increased risk for infection, such as persons with HIV, men who have sex with men, and people whose communities have an elevated prevalence of the disease.

VISION AND HEARING

Undetected but correctable vision (Chapter 391) and hearing (Chapter 396) problems are common in older adults and can be discovered by asking about problems and performing simple tests of visual acuity and hearing. Unfortunately, evidence is limited to show that regular screening leads to measurable benefits in function. Regular visual acuity testing is recommended for older adults by many organizations, but a large trial did not find any lasting benefits of screening, despite detecting many correctable causes of vision problems. The USPSTF concluded that evidence was insufficient[A16] to recommend routine vision or hearing screening.[22,23]

BEHAVIORAL INTERVENTIONS

Lifestyle factors contribute to a large proportion of preventable deaths in the United States. Brief interventions are effective for some behaviors such as smoking and problem drinking, but changing other behaviors usually requires more intensive approaches. The *5 As* framework—ask, assess, advise, assist, and arrange—which was developed from smoking cessation research, provides a useful framework for counseling.

TOBACCO USE

Brief interventions can produce small but clinically important increases in quit rates among people who use tobacco. Effects increase with more intensive counseling and support, including the use of medication (Chapter 363).

MISUSE OF ALCOHOL AND DRUGS

The USPSTF recommends screening all adults 18 years or older for alcohol misuse (Chapter 364) with one of three tools: the 10-question AUDIT instrument, its 3-question version AUDIT-C (http://www.integration.samhsa.gov/images/res/tool_auditc.pdf), or a single question: "How many times in the past year have you had five (for men) or four (for women and adults over 65 years old) or more drinks in a day?" Brief multicontact behavioral interventions can successfully reduce alcohol consumption in at-risk adults who drink. The USPSTF also recommends screening for unhealthy drug use (Chapter 365), primarily based on the benefits of treating people with opioid use disorder.[24]

DIET AND PHYSICAL ACTIVITY

Counseling to promote a healthful diet (Chapter 13) and to promote physical activity (Chapter 14) can reduce the intake of saturated fat, increase the consumption of fruits and vegetables, and increase weekly physical activity. Studies of counseling also demonstrate small but potentially important improvements in CVD risk factors, including blood pressure, low-density lipoprotein cholesterol, and adiposity. Effects are most consistent with more intensive counseling (multiple sessions with trained counselors) and in higher-risk patients, such as those who have overweight or obesity or CVD risk factors (Chapters 14 and 13).

INJURY PREVENTION

Motor vehicle injuries are the leading cause of years of potential life lost before age 65 years. In older persons, falls are a leading cause of unintentional injury and can be reduced with exercise in community-dwelling seniors and targeted multicomponent interventions in highest-risk groups (Chapter 24). The USPSTF recommends that women of childbearing age be screened for intimate partner violence (Chapter 223)[25] but found insufficient evidence to recommend screening all elderly or other vulnerable adults for abuse and neglect.

IMMUNIZATIONS

Recommendations regarding immunization (Chapter 15) are regularly updated by the Advisory Committee on Immunization Practices of the CDC (http://www.cdc.gov/vaccines).[26]

Vaccination for COVID-19 is recommended (Chapter 337) for all adults and for children and adolescents 5 to 18 years, including a booster shot for adults. These recommendations are likely to be updated as the virus mutates or immunity wanes.

Annual influenza immunization is recommended for all adults. Pneumococcal vaccination is recommended for adults ages 65 years and older and is also indicated for younger adults with chronic heart, lung, or kidney disease; asthma; diabetes; asplenia and other immune disorders; as well as those who smoke. Two doses of varicella vaccine are recommended for all adults born in the United States after 1980 without other evidence of immunity, and two doses of zoster vaccine are recommended for all adults at age 60 years. Adults should be revaccinated once with the Tdap vaccine (tetanus, diphtheria, acellular pertussis) and every 10 years with Td; if their vaccination history is uncertain, complete primary immunization with two additional doses of Td is recommended. A series of three doses of a vaccine against HPV is recommended for young men and women ages 15 to up to age 26 years (only two doses are required for vaccination at ages 11 to 14 years) to reduce the risk for cervical cancer and genital warts, as well as to decrease transmission of the virus.

PREVENTIVE MEDICATIONS AND SUPPLEMENTS

Aspirin, postmenopausal hormone replacement therapy, breast cancer preventive medications, HIV preexposure prophylaxis (PrEP), and supplements of vitamins or minerals can carry both benefits and risks. Decisions need to consider the likely benefits (which increase with the underlying risk of the disease being prevented), the probability of harm, and the individual preferences of each patient.

ASPIRIN

In men and women without known vascular disease, aspirin reduces the risk for nonfatal myocardial infarction and ischemic stroke, but these benefits are often offset by an increased risk for serious gastrointestinal bleeding and hemorrhagic stroke.[A17] In men and women who have an elevated risk of CVD (10-year risk at least 10%), the benefits of aspirin outweigh risks by a small amount for adults ages 40 to 59 years. As a result, decisions regarding aspirin in this age range should be individualized based on additional consideration of risks and patients' values.[27] By comparison, the USPSTF found evidence that the harms outweigh the benefits in older adults[A18] and recommends against initiating aspirin therapy in adults ages 60 years or older (Chapter 70).

PREVENTIVE MEDICATIONS FOR BREAST CANCER

Tamoxifen, raloxifene, and aromatase inhibitors can reduce the incidence of invasive breast cancer in women at increased risk, but all have some harms. Tamoxifen and raloxifene increase the risk for thromboembolic events and worsen menopausal symptoms, tamoxifen also increases the risk for endometrial cancer (Chapter 184). Aromatase inhibitors worsen menopausal symptoms and are associated with gastrointestinal symptoms and musculoskeletal pain. The USPSTF recommends clinicians discuss the balance of benefits and harms of these medications with women over age 35 years who are at increased risk for breast cancer. Women most likely to benefit are those who are at low risk for the adverse effects of medications and whose 5-year risk of invasive breast cancer is 3% or higher. Online tools can be used to assess this risk (http://www.cancer.gov/bcrisktool/).

POSTMENOPAUSAL HORMONE THERAPY

Estrogen-only therapy in women over the age 50 years reduces the risk for developing diabetes and fractures in the near term, but it is also associated with a higher risk of gallbladder disease, stroke, and venous thromboembolism (Chapter 222).[A19] Combination therapy with estrogen and progestin, by comparison, reduces the risk of diabetes and fractures as well as colorectal cancer, but it increases the risk for invasive breast cancer, coronary heart disease, stroke, pulmonary embolism, gallbladder disease, urinary incontinence, and dementia.[A20] Hormone therapy is an option for younger menopausal women with persistent, troublesome menopausal symptoms (Chapter 222), but the USPSTF recommends against its routine use for preventive purposes.

HIV PREEXPOSURE PROPHYLAXIS

The use of daily tenofovir-based medications reduces the risk of HIV acquisition by about 50% in individuals who are at increased risk of HIV infection (Chapter 356).[A21] Adherence to daily use is a strong predictor of benefit. The USPSTF recommends HIV preexposure prophylaxis for persons at high risk of HIV infection, including persons with serodiscordant partners, who use condoms inconsistently with partners at high risk, or who have had a recent sexually transmitted infection. Preexposure prophylaxis is also recommended for persons who inject drugs and share needles (Chapter 365).[28]

VITAMIN AND MINERAL SUPPLEMENTATION

The USPSTF does not recommend routine use of vitamin or mineral supplements because there is no convincing evidence that multivitamins or individual or paired supplements (e.g., vitamin A, C, and D; folic acid; selenium; or calcium) reduce CVD, cancer, or all-cause mortality in community-dwelling average-risk adults. For vitamin E or beta-carotene, routine supplements are documented to be harmful. The USPSTF found insufficient evidence to support screening for vitamin D deficiency in adults[A22,29] or to suggest the routine use of calcium and vitamin D supplements for the primary prevention of fractures in ambulatory adults.

FUTURE ISSUES

Preventive care recommendations often vary based on a patient's characteristics such as age, sex, gender, and clinical risk factors, including behavior and race or ethnicity. Given well-described epidemiologic differences in the prevalence of diseases and their health impacts, prevention and treatment guidelines will likely become more specific for populations if and when sufficient evidence exists. Genomic testing has the potential for guiding personal recommendations for screening and prevention, but currently available genomic screening in average-risk individuals is limited by an incomplete understanding of the predictive value of specific genotypes in the general population, the uncertain effect of such information on clinical decisions, and concerns about the possible adverse effects of screening (e.g., anxiety, false reassurance, or discrimination). The USPSTF issues an annual report to Congress about research priorities: recent reports have focused on the need for more evidence about adult and child mental health, substance abuse and intimate partner violence, and health equity.[30]

DIET AND NUTRITION

DONALD D. HENSRUD

DIETARY REQUIREMENTS

The recommended dietary allowances for essential nutrients are the average daily level of intake shown to be sufficient to meet the nutrient requirements of nearly all (97 to 98%) healthy people. By comparison, the dietary reference intakes take into consideration the accumulating evidence on the relationships of diet and nutritional status to chronic diseases, such as coronary heart disease, cancer, diabetes, and the other leading causes of death. Dietary reference intakes recommend intake levels that not only prevent deficiencies but also may promote long-term health and disease prevention.

In this way, dietary guidelines have expanded from focusing on preventing deficiencies of isolated nutrients to preventing chronic disease, a goal that is especially important now that about 50% of all adult Americans have one or more preventable chronic diseases and over 70% of adults are overweight or obese. The 2020-2025 Dietary Guidelines for Americans translates average caloric requirements (Table 13-1) into specific recommendations that can reduce the likelihood of becoming overweight or obese.

NUTRITION'S INFLUENCE ON MORTALITY AND MORBIDITY

EVIDENCE OF CONNECTIONS BETWEEN DIET AND DISEASE

Deficiency conditions of specific nutrients have been well documented, but establishing conclusive relationships between diet and chronic diseases often relies on epidemiologic studies that are susceptible to unrecognized confounding and cannot infer causality. Nevertheless, the totality of consistent evidence from large population studies and randomized trials in at-risk individuals have brought clarity to the characteristics of dietary patterns that promote optimal health.

Diet should not be considered in isolation because other lifestyle factors also influence the risk of chronic diseases. The greatest nutritional public health problems in the United States and in many other parts of the world are overweight and obesity, with their associated comorbidities. Body weight is ultimately determined by the balance between energy intake through diet and energy expenditure through physical activity (Chapter 14). Recommendations for health promotion and disease prevention must include diet and physical activity, as well as other lifestyle factors.

DISEASES INFLUENCED BY NUTRITION

Of the 10 leading causes of death in the United States (Table 13-2),[1] 6 are related to diet, 4 to excess alcohol use (Chapter 364), and 6 to obesity (Chapter 201). Major causes of morbidity that often underlie causes of death (e.g., obesity, chronic liver disease, and hypertension) are also directly related to diet and nutrition.

The 2020-2025 Dietary Guidelines for Americans (Table 13-3)[2] outline critical ways for health professionals to help Americans make healthy choices. Although dietary recommendations promulgated by major professional societies for risk reduction and/or management of the major chronic diseases vary somewhat in their details (E-Table 13-1),[3–6] the close agreement among these recommendations enhances their credibility.

Cardiovascular Disease

Of the seven major risk factors for coronary heart disease, four are related to diet: hypercholesterolemia (Chapter 190), hypertension (Chapter 64), obesity (Chapter 201), and diabetes (Chapter 210). Elevated plasma low-density lipoprotein (LDL) cholesterol is a strong risk factor for coronary heart disease and is raised by increasing consumption of dietary saturated fat and *trans* fat. *Trans* fat also lowers high-density lipoprotein (HDL) cholesterol. Saturated fat is found in meat, full-fat dairy products, and tropical oils. *Trans* fat, which comes almost entirely from partially hydrogenated oils and has no health benefits, was removed from processed foods in 2018 by the U.S. Food and Drug Administration. Less emphasis is placed on limiting dietary cholesterol in recent guidelines because dietary cholesterol has a lesser effect on LDL cholesterol than saturated fat and is often found in the same foods. Limiting foods that contain saturated fat also limits dietary cholesterol. LDL cholesterol levels can be lowered by substituting healthier unsaturated fats (polyunsaturated or monounsaturated oils) or carbohydrates (preferably whole

The 2020-2025 Dietary Guidelines for Americans (Table 13-3)[2] outline critical ways for health professionals to help Americans make healthy choices. Although dietary recommendations promulgated by major professional societies for risk reduction and/or management of the major chronic diseases vary somewhat in their details (E-Table 13-1),[3–6] the close agreement among these recommendations enhances their credibility.

Cardiovascular Disease

Of the seven major risk factors for coronary heart disease, four are related to diet: hypercholesterolemia (Chapter 190), hypertension (Chapter 64), obesity (Chapter 201), and diabetes (Chapter 210). Elevated plasma low-density lipoprotein (LDL) cholesterol is a strong risk factor for coronary heart disease and is raised by increasing consumption of dietary saturated fat and *trans* fat. *Trans* fat also lowers high-density lipoprotein (HDL) cholesterol. Saturated fat is found in meat, full-fat dairy products, and tropical oils. *Trans* fat, which comes almost entirely from partially hydrogenated oils and has no health benefits, was removed from processed foods in 2018 by the U.S. Food and Drug Administration. Less emphasis is placed on limiting dietary cholesterol in recent guidelines because dietary cholesterol has a lesser effect on LDL cholesterol than saturated fat and is often found in the same foods. Limiting foods that contain saturated fat also limits dietary cholesterol. LDL cholesterol levels can be lowered by substituting healthier unsaturated fats (polyunsaturated or monounsaturated oils) or carbohydrates (preferably whole

ABSTRACT

The relationships of diet and nutrition with health and disease have evolved over time. Rather than focusing on isolated nutrients and preventing nutritional deficiencies, dietary guidelines now emphasize healthy dietary patterns to prevent chronic disease and promote health. The optimum dietary pattern is higher in vegetables, fruits, whole grains, low- or nonfat dairy, seafood, legumes, and nuts; it is also lower in red and processed meats, salt, sugar-sweetened foods and drinks, refined grains, and alcohol. Each of these recommendations is based on increasingly solid evidence.

E-TABLE 13-1 DIETARY GUIDELINES PROMULGATED BY NATIONAL ORGANIZATIONS*

INDICATION OR OBJECTIVE	U.S. DEPARTMENT OF AGRICULTURE AND DEPARTMENT OF HEALTH AND HUMAN SERVICES: DIETARY GUIDELINES FOR AMERICANS (2020-2025)*	2019 ACC/AHA GUIDELINE ON THE PRIMARY PREVENTION OF CARDIOVASCULAR DISEASE: EXECUTIVE SUMMARY†	AMERICAN CANCER SOCIETY (2020)‡	AMERICAN DIABETES ASSOCIATION (2019)§
	GENERAL HEALTH PROMOTION AND DISEASE PREVENTION	*HEART DISEASE PREVENTION*	*CANCER PREVENTION*	*DIABETES PREVENTION AND TREATMENT*
NUTRIENT/FOOD GROUP				
Total energy	Stay within calorie needs at each life stage	In individuals with overweight and obesity, weight loss is recommended Counseling and comprehensive lifestyle interventions, including calorie restriction, are recommended for achieving and maintaining weight loss	Achieve and maintain a healthy body weight throughout life	Adults with overweight/obesity and prediabetes or diabetes should include an individualized eating plan in a format that results in an energy deficit
Fruits and vegetables	Include 1½-2½ cup-equivalents of fruits, at least half from whole fruit rather than juice, and 2-4 cup-equivalents of a variety of vegetables from all the subgroups daily, depending on calorie level	Emphasize vegetables and fruits	Include a variety of vegetables—dark green, red, and orange, fiber-rich legumes (beans and peas), and others; include fruits, especially whole fruits with a variety of colors	
Meat	Choose a variety of protein foods, including 5-7 oz-equivalents of seafood, lean meat and poultry, eggs, beans, peas, lentils, and nuts, seeds, and soy products	Minimize processed meats	Limit or do not include red and processed meats	
Dairy	3 cup-equivalents daily of fat-free or low-fat dairy including milk, yogurt, cheese, and/or fortified soy beverages			
Grains, fiber	Consume 5-10 oz-equivalents daily with at least half as whole grains	Emphasize whole grains	Include whole grains Limit or do not include refined grain products	Consume at least the amount of fiber recommended by the Dietary Guidelines Achieve fiber intake preferably through food
Fat	Include 22-44 g daily of PUFA and MUFA oils Limit saturated fats and *trans* fats			Macronutrient distribution should be based on individualized assessment
Saturated fats	Limit to <10% of daily calories, by replacing them with monounsaturated and polyunsaturated fats	Replace saturated fat with dietary monounsaturated and polyunsaturated fats		Replace saturated fat with unsaturated fats
Trans-fats	Limit	Avoid		Minimize to the greatest extent possible
Cholesterol	Keep as low as possible	Reduce cholesterol intake		
Carbohydrates		Minimize refined carbohydrates		Macronutrient distribution should be based on individualized assessment Replace refined carbohydrates and added sugars with whole grains, legumes, vegetables, and fruits
Sugar	<10% of calories	Minimize sweetened beverages	Limit or do not include sugar-sweetened beverages	Minimize added sugars and replace sugar-sweetened beverages with water as often as possible
Protein	Choose a variety of protein foods, which include eggs, beans, peas, lentils, soy products, and unsalted nuts and seeds (for more, see Meat)	Emphasize fish, legumes, and nuts		Macronutrient distribution should be based on individualized assessment
Alcohol	Up to 2 drinks/day for men and up to 1 drink/day for women; persons in special circumstances (e.g., pregnancy, history of alcoholism) should abstain		Best not to consume alcohol. People who choose to drink alcohol should limit their consumption to no more than 1 drink/day for women and 2 drinks/day for men	Adults with diabetes or prediabetes who drink alcohol do so in moderation (two drinks or less per day for adult men and one drink or less per day for adult women) Glucose monitoring after drinking alcohol beverages to reduce hypoglycemic risk
Processed food			Limit or do not include processed foods	Choose whole foods over highly processed foods to the extent possible
Sodium	Reduce daily sodium intake to less than 2300 mg	Reduce sodium intake		<2300 mg/day

grains) for saturated fat. LDL cholesterol can also be lowered modestly by increasing the intake of soluble fiber and phytosterols from legumes, fruits, vegetables, and flax seed, as well as by consuming proteins and isoflavones from soy foods.

TABLE 13-3 DIETARY GUIDELINES FOR AMERICANS, 2020-2025: KEY RECOMMENDATIONS

1. Follow a healthy dietary pattern at every life stage.
   - For about the first 6 months of life, exclusively feed infants human milk.
   - At about 6 months, introduce infants to nutrient-dense complementary foods.
   - From 12 months through older adulthood, follow a healthy dietary pattern.
2. Customize and enjoy nutrient-dense food and beverage choices to reflect personal preferences, cultural traditions, and budgetary considerations.
3. Focus on meeting food group needs with nutrient-dense foods and beverages, and stay within calorie limits.
   - The core elements that make up a healthy dietary pattern include:
     - Vegetables of all types—dark green; red and orange; beans, peas, and lentils; starchy; and other vegetables
     - Fruits, especially whole fruit
     - Grains, at least half of which are whole grain
     - Dairy, including fat-free or low-fat milk, yogurt, and cheese, and/or lactose-free versions and fortified soy beverages and yogurt as alternatives
     - Protein foods, including lean meats, poultry, and eggs; seafood; beans, peas, and lentils; and nuts, seeds, and soy products
     - Oils, including vegetable oils and oils in food, such as seafood and nuts
4. Limit foods and beverages higher in added sugars, saturated fat, and sodium, and limit alcoholic beverages.
   - Added sugars—Less than 10% of calories per day starting at age 2. Avoid foods and beverages with added sugars for those less than 2 years of age
   - Saturated fat—Less than 10% of calories per day starting at age 2
   - Sodium—Less than 2300 milligrams per day, and even less for children younger than age 14
   - Alcoholic beverages—Adults of legal drinking age can choose not to drink or to drink in moderation by limiting intake to 2 drinks or less in a day for men and 1 drink or less in a day for women

Adapted from the *Dietary Guidelines for Americans, 2020-2025*. 9th ed. U.S. Department of Agriculture and U.S. Department of Health and Human Services. December 2020. https://www.dietaryguidelines.gov/. Accessed January 24, 2022.

Diet also can influence the risk of coronary heart disease in ways independent of LDL cholesterol and traditional risk factors, such as inflammation, oxidative stress, endothelial function, insulin sensitivity, and others. Consistent evidence from meta-analyses of large cohort studies has shown decreased cardiovascular and total mortality with increasing consumption of fruits and vegetables, whole grains, and nuts, as well as decreased incident coronary heart disease and total mortality from fish and olive oil.[7,8] Randomized trials are generally consistent with cohort studies, and a Mediterranean dietary pattern (Fig. 13-1) composed of many of these food groups can favorably affect cardiovascular risk factors and outcomes.[A1–A3] Diets such as the Dietary Approaches to Stop Hypertension (DASH) diet (Table 13-4) can reduce the incidence of cardiovascular disease by 30%.[A4] Higher-carbohydrate diets also can lower the risk of coronary heart disease in men by 20%, whereas the higher–unsaturated fat and higher-protein diets can reduce the risk by 30%.

Sodium intake clearly influences blood pressure, but much controversy has surrounded whether reducing sodium intake would truly be beneficial. In a cluster randomized trial in China, providing a salt substitute that was 75% sodium chloride and 25% potassium chloride to persons over age 60 years or with a history of stroke reduced cardiovascular events and death by 12 to 13% over a mean follow-up of 4.75 years.[A5] These data support the salt recommendations in Table 13-3.[9]

Moderate consumption of alcohol, defined as no more than one drink daily for women and two for men, has been associated with reduced risk of coronary heart disease, primarily by raising HDL cholesterol, inhibiting platelet aggregation, and stimulating fibrinolytic activity. National dietary data indicate that added sugar is associated with increased cardiovascular mortality. In addition, consumption of red and particularly processed meat has been associated with increased cardiovascular and total mortality.[10]

Cancer

About one third of cancers are due to suboptimal habits in diet,[11] physical activity, and weight management. Because cancer consists of many different conditions that share a common feature of uncontrolled abnormal cell division, risk factors, including diet, vary among different types of cancer. Nutrients, non-nutritive dietary constituents, and nutritional status can influence the risk for cancer through many different mechanisms, such as free radical scavenging

The Mediterranean Diet

Food/Food Group	Recommended Intake*	Tips
Vegetables	4 or more servings each day (one portion each day should be raw vegetables)	Eat a variety of colors and textures; a serving is 1 cup raw or ½ cup cooked vegetables.
Fruits	3 or more servings each day	Make fruit your dessert
Grains	4 or more servings each day	Choose mostly whole grains. 1 serving = 1 slice bread or ½ cup cooked oatmeal
Fats/Oils	Olive oil: 4 Tablespoons or more each day	Choose extra virgin olive oil and use in salad dressings and cooking; choose avocado or natural peanut butter instead of butter or margarine
Dried Beans/Nuts/Seeds	Nuts/Seeds: 3 or more servings each week Beans/Legumes: 3 or more servings each week	1 ounce or 1 serving = 23 almonds or 14 walnut halves; 1 serving of beans = ½ cup
Fish and Seafood	2-3 times each week	Choose salmon, sardines, and tuna, which are rich in omega-3 fatty acids
Herbs and Spices	Use daily	Season foods with herbs, garlic, onions, and spices instead of salt
Yogurt/Cheese/Egg and Poultry	Choose daily to weekly	Choose low-fat yogurt and cheeses; choose skinless chicken or turkey instead of red meat
Alcohol/Wine	Men: 1-2 glasses each day Women: 1 glass each day	Always ask your clinician if alcohol is ok for you to consume.

FIGURE 13-1. Mediterranean Diet. Choosing a diet similar to one eaten by people living around the Mediterranean Sea may lower the risk of cardiovascular disease and have additional health benefits. The diet is mostly plant-based with high amounts of fresh vegetables, fruits, nuts, dried beans, olive oil, and fish. *Serving sizes should be individualized to meet energy and nutrient needs. Red meats, processed meats, and sweets should be limited. (Adapted from Mediterranean Diet. https://www.nutrition.va.gov/docs/UpdatedPatientEd/Mediterraneandiet.pdf. U.S. Department of Veterans Affairs. Accessed January 24, 2022.)

TABLE 13-4 DIETARY APPROACHES TO STOP HYPERTENSION (DASH)

FOOD GROUP	SERVINGS PER DAY 1600 CALORIES	2000 CALORIES	2600 CALORIES	SERVING SIZES	EXAMPLES AND NOTES	SIGNIFICANCE OF EACH FOOD GROUP TO THE DASH EATING PLAN
Grains*	6	6–8	10–11	1 slice bread 1 oz dry cereal† ½ cup cooked rice, pasta, or cereal	Whole wheat bread and rolls, whole wheat pasta, English muffin, pita bread, bagel, cereals, grits, oatmeal, brown rice, unsalted pretzels, and popcorn	Major sources of energy and fiber
Vegetables	3–4	4–5	5–6	1 cup raw leafy vegetable ½ cup cut-up raw or cooked vegetable ½ cup vegetable juice	Broccoli, carrots, collards, green beans, green peas, kale, lima beans, potatoes, spinach, squash, sweet potatoes, tomatoes	Rich sources of potassium, magnesium, and fiber
Fruits	4	4–5	5–6	1 medium fruit ¼ cup dried fruit ½ cup fresh, frozen, or canned fruit ½ cup fruit juice	Apples, apricots, bananas, dates, grapes, oranges, grapefruit, grapefruit juice, mangoes, melons, peaches, pineapples, raisins, strawberries, tangerines	Important sources of potassium, magnesium, and fiber
Fat-free or low-fat milk and milk products	2–3	2–3	3	1 cup milk or yogurt 1½ oz cheese	Fat-free (skim) or low-fat (1%) milk or buttermilk; fat-free, low-fat, or reduced-fat cheese; fat-free or low-fat regular or frozen yogurt	Major sources of calcium and protein
Lean meats, poultry, and fish	3–6	6 or less	6	1 oz cooked meats, poultry, or fish 1 egg‡	Select only lean meats; trim away visible fat; broil, roast, or poach; remove skin from poultry	Rich sources of protein and magnesium
Nuts, seeds, and legumes	3 per week	4–5 per week	1	⅓ cup or 1½ oz nuts 2 Tbsp peanut butter 2 Tbsp or ½ oz seeds ½ cup cooked legumes (dry beans and peas)	Almonds, hazelnuts, mixed nuts, peanuts, walnuts, sunflower seeds, peanut butter, kidney beans, lentils, split peas	Rich sources of energy, magnesium, protein, and fiber
Fats and oils§	2	2–3	3	1 tsp soft margarine 1 tsp vegetable oil 1 Tbsp mayonnaise 2 Tbsp salad dressing	Soft margarine, vegetable oil (such as canola, corn, olive, or safflower), low-fat mayonnaise, light salad dressing	The DASH study had 27% of calories as fat, including fat in or added to foods
Sweets and added sugars	0	5 or less per week	<2	1 Tbsp sugar 1 Tbsp jelly or jam ½ cup sorbet, gelatin 1 cup lemonade	Fruit-flavored gelatin, fruit punch, hard candy, jelly, maple syrup, sorbet and ices, sugar	Sweets should be low in fat

*Whole grains are recommended for most grain servings as a good source of fiber and nutrients.
†Serving sizes vary between ½ cup and 1¼ cups, depending on cereal type. Check the product's Nutrition Facts label.
‡Because eggs are high in cholesterol, limit egg yolk intake to no more than four per week; two egg whites have the same protein content as 1 oz of meat.
§Fat content changes serving amount for fats and oils. For example, 1 Tbsp of regular salad dressing equals one serving; 1 Tbsp of a low-fat dressing equals one-half serving; 1 Tbsp of a fat-free dressing equals zero servings.
oz = ounce; Tbsp = tablespoon; tsp = teaspoon.
Adapted from National Heart, Lung and Blood Institute. In brief: your guide to lowering your blood pressure with DASH. NIH Publication No. 06-5834. https://www.nhlbi.nih.gov/files/docs/public/heart/dash_brief.pdf. Accessed January 24, 2022.

and DNA repair. Supplementation with individual nutrients has had limited success in preventing and treating cancer. Therefore, as with heart disease, a focus on foods and dietary patterns provides the best nutritional approach to preventing cancer.

Obesity (Chapter 201) is now recognized as a major risk factor for at least 12 cancers, perhaps by elevating serum levels of insulin and leptin, inducing insulin resistance, and creating a chronic inflammatory state (Chapter 164). Excess alcohol intake (Chapter 364) also increases the risk for many cancers, including liver, breast, and the entire gastrointestinal tract.

Lung Cancer

Although the most important causal factor in the number-one cancer killer, lung cancer (Chapter 177), is cigarette smoking, consumption of fruit is inversely associated with the risk of lung cancer in both smokers and nonsmokers. Two large, randomized trials of supplementation with β-carotene reported increased mortality from lung cancer and all causes, primarily in smokers and former smokers, so β-carotene supplementation should be avoided.

Breast Cancer

The number-two cause of cancer deaths in women is breast cancer (Chapter 183). Postmenopausal breast cancer is positively associated with obesity, especially when excess adiposity is located predominantly in the abdomen. Paradoxically, the risk of premenopausal breast cancer is decreased with obesity. Alcohol increases and lactation probably decreases the risk of both types of breast cancer.

Colorectal Cancer

Colorectal cancer (Chapter 179) is the third leading cause of cancer mortality in men and women. The risk for colorectal cancer correlates positively with the intake of red and processed meats, obesity, and alcohol. The World Health Organization has classified processed meat as a carcinogen and red meat as a probable carcinogen. Foods that contain dietary fiber (as opposed to fiber per se), dairy products, and calcium appear to decrease risk.[12,13]

Prostate Cancer

Although studies have evaluated different dietary factors on the risk of prostate cancer, the clearest risk factor is obesity.

Liver Cancer

The strongest risk factor for liver cancer is alcohol, but obesity also increases risk in part via nonalcoholic fatty liver disease (Chapter 138). Aflatoxins are a strong risk factor, primarily outside the United States where they are more prevalent in the food supply. Coffee appears to be protective against liver cancer.

Pancreas Cancer

Associations exist between pancreas cancer and various dietary factors, but causality is not clear except for obesity, which increases risk.

Recommendations

Although there are differences among dietary risks for different cancers, the American Cancer Society Guidelines for Cancer Prevention are generally

similar to other major dietary guidelines: consuming a plant-based diet, regular physical activity, and maintenance of a healthy body weight. Alcohol intake is the primary difference between guidelines to prevent heart disease, for which moderate consumption may be beneficial, and guidelines to prevent cancer, for which consumption increases risk even at low levels for some cancers, such as breast cancer and head and neck cancer. Randomized trials with isolated nutrients including carotenoids, vitamins C and E, folic acid, selenium, and even dietary fiber have not shown a benefit for reducing the risk of cancer. Whole plant foods contain hundreds of different vitamins, nutrients, and other phytochemicals that may collectively reduce the risk of cancer more than specific nutrients.

Hypertension

Elevated blood pressure (Chapter 64) is a major risk factor for stroke (Chapters 376 and 377), coronary heart disease (Chapter 40), heart failure (Chapter 45), peripheral vascular disease (Chapter 65), and renal disease (Chapter 116). Five lifestyle factors can reduce blood pressure: weight loss if overweight or obese, the DASH diet, increased physical activity, sodium restriction, and alcohol restriction. Obesity, especially abdominal obesity, is associated with hypertension, and weight reduction is the strongest lifestyle change that decreases blood pressure. The DASH diet (see Table 13-4) can lower blood pressure as much as drug treatment (11.6/5.3 mm Hg) in individuals with hypertension.

Diabetes Mellitus

Type 2 diabetes mellitus (Chapter 210) is strongly associated with obesity, especially abdominal obesity, so maintenance of a desirable body weight throughout life is of major importance in both preventing and treating type 2 diabetes. Sugar consumption does not have a large impact on developing diabetes, except to the extent that it may promote weight gain. However, sugar-sweetened beverages contribute to weight gain and an increased risk of type 2 diabetes. A high–glycemic index (a measure of the amount a food increases blood glucose) diet also increases risk. Red and particularly processed meats increase the risk of type 2 diabetes. Coffee intake decreases the risk of diabetes in a dose-dependent fashion. A Mediterranean dietary pattern (see Fig. 13-1) higher in healthy fat can lead to slightly better glucose control than a high-carbohydrate diet. However, a higher-carbohydrate diet can still be utilized, provided that calories are controlled and preferably whole grains are emphasized. An overall healthy eating pattern helps also reduce the risk for cardiovascular disease, which is the main cause of death in patients with diabetes.

Osteoporosis

Adequate intake of calcium, vitamin D, and protein in childhood is important for achieving optimal peak bone mass in adulthood and preventing osteoporosis (Chapter 225) later in life. Dairy products are the primary source of calcium for most children. Adults should try to achieve the recommended dietary allowance for calcium (1000 mg/day until age 50 for women and age 70 for men, then 1200 mg/day), primarily through dietary calcium with supplemental calcium as necessary. The optimum intake and blood level of vitamin D are controversial. Adults should try to achieve an intake of vitamin D at the level of the recommended dietary allowance (600 IU/day until age 70, then 800 IU/day). Fruit and vegetable intake is associated with increased bone density through various mechanisms. Vitamin K, magnesium, and zinc are involved in bone metabolism, but supplementation has not been demonstrated to be beneficial to bone health. Excessive supplementation with vitamin A increases the risk of fracture, as does excess alcohol consumption.

Other Conditions

Obesity

Obesity is the most prevalent nutritional disorder in the United States (see Chapter 201). The metabolic syndrome (a constellation that includes obesity with a large waist circumference, increased levels of serum glucose and triglycerides, high blood pressure, and a reduced HDL cholesterol level) is strikingly prevalent in the United States and is a major risk factor for coronary heart disease, cancer, type 2 diabetes, and hypertension (Chapter 64). Globally, and even in some locales in the United States, malnutrition (Chapter 198) may exist in close proximity to overweight and obesity.[14,15]

Intestinal Diverticular Disease

Low dietary fiber intake causes constipation (Chapter 118), and it is thought to be a cause of intestinal diverticular disease (Chapter 128).

Dementia

Although physical activity is the strongest lifestyle factor that is associated with the avoidance of cognitive decline, dietary factors also play a role. Observational studies suggest that Mediterranean and DASH diets may help preserve cognitive function, in part by reducing the risk of cerebrovascular disease. Limited data raise the probability that even more emphasis on increasing the intake of green leafy vegetables, berries, fish, nuts, and olive oil, as well as limiting the intake of red meats, pastries, and sweets, may be even more beneficial.

Congenital Neural Tube Defects

Inadequate maternal folic acid intake (Chapter 199) has been definitively proven to be a major risk factor for congenital neural tube defects, such as spina bifida and myelomeningocele. For this reason, cereal and grain products have been fortified with folic acid in the United States since 1998, and supplementation with folic acid is recommended in all women capable of becoming pregnant (Chapter 219).

Dietary Supplements

Relatively few dietary supplements have demonstrated benefit in preventing disease. Although higher blood concentrations of vitamin C, carotenoids, and vitamin E are associated with lower mortality, this finding appears to be because they are markers of a better diet.[16] Meta-analyses of randomized, controlled trials of antioxidants have reported increased total mortality from vitamin A, vitamin E, and β-carotene. Vitamin D and calcium are necessary for adequate bone health, and vitamin D may have other health benefits, but the evidence is inconclusive. For example, vitamin D supplementation does not improve musculoskeletal health,[A6] reduce the risk of depression,[A7] or reduce the risk of cancer, cardiovascular disease, or mortality in adults.[A8] Although multivitamins are one of the most widely used dietary supplements, with over one third of Americans taking them, there is little evidence that they prevent cardiovascular disease or cancer. Fish consumption is associated with decreased cardiovascular disease, yet randomized trials have found no benefit from omega-3 supplementation,[A9] with the exception of icosapent ethyl (a highly purified eicosapentaenoic acid ethyl ester at 4 g daily), which can reduce future cardiovascular events by 25% in patients who already have very high-risk cardiovascular disease and have elevated serum triglyceride levels (135 to 499 mg/dL).[A10] By comparison, dietary supplements with vitamins C and E, zinc, copper, lutein, and zeaxanthin may benefit patients with early macular degeneration.[A11]

TRANSLATING EVIDENCE INTO DIETARY CHANGE

The evidence is strong that dietary habits can influence the incidence and severity of many incapacitating or lethal diseases.[17–19] No justification exists for the belief that modification of the "usual" American diet is unnecessary or futile. The following statement from the Scientific Report of the 2020 Dietary Guidelines Advisory Committee concisely outlines the optimal dietary pattern based on current evidence: "Common characteristics of dietary patterns associated with positive health outcomes include higher intake of vegetables, fruits, legumes, whole grains, low- or non-fat dairy, lean meat and poultry, seafood, nuts, and unsaturated vegetable oils and low consumption of red and processed meats, sugar-sweetened foods and drinks, and refined grains."[20] Various organizations have provided dietary recommendations generally consistent with this statement (see E-Table 13-1). The U.S. Departments of Agriculture and of Health and Human Services have developed and periodically revised the Dietary Guidelines for Americans (see Table 13-3). The Dietary Guidelines list three dietary patterns of eating that are consistent with the guidelines and people can use as a practical template to follow: the Healthy U.S., Healthy Vegetarian, and Healthy Mediterranean. A food guidance system, now called MyPlate (Fig. 13-2), is part of a larger communications initiative to help consumers make better food choices. Physicians can influence their patients' health by encouraging them to optimize their dietary habits and providing them with instructional materials, assistance from dietitians, or behavioral counseling,[A12] particularly in patients who are overweight, obese, or have other cardiovascular risk factors.[21]

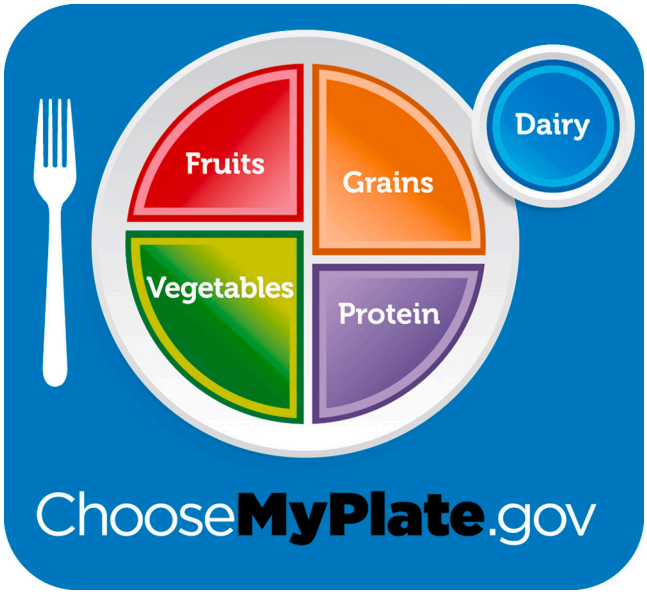

FIGURE 13-2. U.S. Department of Agriculture's MyPlate. MyPlate illustrates that a substantial proportion of dietary intake should be derived from vegetables, fruits, and grains, as contrasted with many Americans' expectation that protein sources should dominate. For more information, see www.ChooseMyPlate.gov.

14 PHYSICAL ACTIVITY

WILLIAM E. KRAUS

DEFINITIONS

Physical activity can be broadly defined as bodily movement produced by skeletal muscles. *Exercise* refers to the subset of physical activity involving a structured program to improve physical fitness. *Health-enhancing physical activity* refers to the subset of physical activities that result in health benefits—generally activity involving large muscle groups of the body and substantial expenditures of energy. The two most important types of health-enhancing physical activity are moderate- to vigorous-intensity aerobic physical activity and moderate- to vigorous-intensity muscle strengthening activity.

TABLE 14-1 EXAMPLES OF MET LEVEL REQUIREMENTS

PHYSICAL ACTIVITY	MET	ACTIVITIES OF DAILY LIVING
LIGHT-INTENSITY ACTIVITIES	**<3**	**LIGHT ACTIVITIES**
Sleeping	0.9	Bathing in tub/eating
Watching television	1.0	Writing, desk work, typing
Walking, 1.7 mph (2.7 km/h), level ground, strolling, very slow	2.3	Light housework Warm shower - sitting
Walking, 2.5 mph (4 km/h)	2.9	Fixing meals
MODERATE-INTENSITY ACTIVITIES	**3 TO 6**	**MODERATE ACTIVITIES**
Bicycling, stationary, 50 watts, very light effort	3.0	Washing floors
Walking 3.0 mph (4.8 km/h)	3.3	Warm shower - standing
Calisthenics, home exercise, light or moderate effort general	3.5	Grocery shopping/vacuuming
Walking 3.4 mph (5.5 km/h)	3.6	Mowing lawn - riding
Bicycling, <10 mph (km/h), leisure, to work or for pleasure	4.0	Gardening - weeding and raking Gardening - digging
Bicycling, stationary, 100 watts, light effort	5.5	Snow shoveling
VIGOROUS-INTENSITY ACTIVITIES	**>6**	**VIGOROUS ACTIVITIES**
Jogging, general	7.0	Mowing lawn - walking
Calisthenics (e.g., push-ups, sit-ups, pull-ups, jumping jacks), heavy, vigorous effort	8.0	Chopping wood
Running jogging, in place	8.0	Carpentry work
Rope jumping	10.0	

MET = metabolic equivalents.
Data from St. Mary's General Hospital.

Regular physical activity improves *health-related physical fitness*—the physiologic components of fitness that influence the risk of disease, functional limitations, disability, and premature mortality. These components include cardiorespiratory endurance (aerobic capacity); skeletal muscle strength, power, and endurance; body composition and bone strength; balance, flexibility, and reaction time.

The primary attributes of physical activity are *type* (mode), *frequency, duration*, and *intensity*. Types of physical activity (e.g., walking, swimming, lifting, stretching) are grouped according to their main physiologic effects into well-known categories: *aerobic* (or "cardio"), *muscle strengthening, flexibility*, and *balance*. Intensity is the effort level during activity. For aerobic activity, the *absolute intensity* is measured in metabolic equivalents (METs). One MET is the resting metabolic rate, which is commonly taken to be 3.5 mL O_2/kg/minute in adults. The *relative intensity* is measured as the percentage of oxygen uptake reserve (aerobic capacity) required to perform an activity (Table 14-1). In practice, the generally linear relationship between heart rate and oxygen uptake makes it reasonable to use the heart rate to monitor the relative intensity of exercise. When the heart rate is not monitored, options for estimating relative intensity (Table 14-2) include the "talk test" and Rating of Perceived Exertion scale, where 6 equals no exertion and 20 equals maximal exertion.

The *volume* (or amount) of activity is the product of frequency, duration, and intensity. Volume can be measured (e.g., by questionnaires) as MET-minutes per week (a sum of the MET intensity of all activities multiplied by the minutes each activity is performed). Volume can also be assessed using wearable devices, such as accelerometers, which are calibrated to translate body movement into measures of volume.

14 PHYSICAL ACTIVITY

WILLIAM E. KRAUS

DEFINITIONS

Physical activity can be broadly defined as bodily movement produced by skeletal muscles. *Exercise* refers to the subset of physical activity involving a structured program to improve physical fitness. *Health-enhancing physical activity* refers to the subset of physical activities that result in health benefits—generally activity involving large muscle groups of the body and substantial expenditures of energy. The two most important types of health-enhancing physical activity are moderate- to vigorous-intensity aerobic physical activity and moderate- to vigorous-intensity muscle strengthening activity.

TABLE 14-1 EXAMPLES OF MET LEVEL REQUIREMENTS

PHYSICAL ACTIVITY	MET	ACTIVITIES OF DAILY LIVING
LIGHT-INTENSITY ACTIVITIES	**<3**	**LIGHT ACTIVITIES**
Sleeping	0.9	Bathing in tub/eating
Watching television	1.0	Writing, desk work, typing
Walking, 1.7 mph (2.7 km/h), level ground, strolling, very slow	2.3	Light housework Warm shower - sitting
Walking, 2.5 mph (4 km/h)	2.9	Fixing meals
MODERATE-INTENSITY ACTIVITIES	**3 TO 6**	**MODERATE ACTIVITIES**
Bicycling, stationary, 50 watts, very light effort	3.0	Washing floors
Walking 3.0 mph (4.8 km/h)	3.3	Warm shower - standing
Calisthenics, home exercise, light or moderate effort general	3.5	Grocery shopping/vacuuming
Walking 3.4 mph (5.5 km/h)	3.6	Mowing lawn - riding
Bicycling, <10 mph (km/h), leisure, to work or for pleasure	4.0	Gardening - weeding and raking Gardening - digging
Bicycling, stationary, 100 watts, light effort	5.5	Snow shoveling
VIGOROUS-INTENSITY ACTIVITIES	**>6**	**VIGOROUS ACTIVITIES**
Jogging, general	7.0	Mowing lawn - walking
Calisthenics (e.g., push-ups, sit-ups, pull-ups, jumping jacks), heavy, vigorous effort	8.0	Chopping wood
Running jogging, in place	8.0	Carpentry work
Rope jumping	10.0	

MET = metabolic equivalents.
Data from St. Mary's General Hospital.

Regular physical activity improves *health-related physical fitness*—the physiologic components of fitness that influence the risk of disease, functional limitations, disability, and premature mortality. These components include cardiorespiratory endurance (aerobic capacity); skeletal muscle strength, power, and endurance; body composition and bone strength; balance, flexibility, and reaction time.

The primary attributes of physical activity are *type* (mode), *frequency, duration*, and *intensity*. Types of physical activity (e.g., walking, swimming, lifting, stretching) are grouped according to their main physiologic effects into well-known categories: *aerobic* (or "cardio"), *muscle strengthening, flexibility*, and *balance*. Intensity is the effort level during activity. For aerobic activity, the *absolute intensity* is measured in metabolic equivalents (METs). One MET is the resting metabolic rate, which is commonly taken to be 3.5 mL O_2/kg/minute in adults. The *relative intensity* is measured as the percentage of oxygen uptake reserve (aerobic capacity) required to perform an activity (Table 14-1). In practice, the generally linear relationship between heart rate and oxygen uptake makes it reasonable to use the heart rate to monitor the relative intensity of exercise. When the heart rate is not monitored, options for estimating relative intensity (Table 14-2) include the "talk test" and Rating of Perceived Exertion scale, where 6 equals no exertion and 20 equals maximal exertion.

The *volume* (or amount) of activity is the product of frequency, duration, and intensity. Volume can be measured (e.g., by questionnaires) as MET-minutes per week (a sum of the MET intensity of all activities multiplied by the minutes each activity is performed). Volume can also be assessed using wearable devices, such as accelerometers, which are calibrated to translate body movement into measures of volume.

ABSTRACT

Regular physical activity has numerous and substantial health benefits—both preventive and therapeutic. Major preventive health benefits include reduced risk of all-cause mortality, coronary heart disease, hypertension, stroke, colon cancer, breast cancer, type 2 diabetes, and fall-related fractures. The marginal benefit of even low physical activity is large, and the marginal benefit actually decreases with greater amounts of activity. The two most importance types of health-enhancing physical activity are moderate- to vigorous-intensity aerobic activity, which has a curvilinear dose-response relationship with health outcomes, and moderate- to vigorous-intensity muscle strengthening activity. Public health guidelines recommend the equivalent of at least 150 minutes of moderate-intensity aerobic activity each week, as well as muscle-strengthening activities on at least two days each week. Unfortunately, only about 20% of American adults currently meet both guidelines. Although physical activity involves risks of adverse events—primarily musculoskeletal injuries—the risk is low, especially if activity increases gradually over time. Health care providers can play an important role in promoting appropriate physical activity in their patients.

TABLE 14-2 CRITERIA FOR ASSESSING RELATIVE AND ABSOLUTE INTENSITY OF AEROBIC ACTIVITY

	RELATIVE INTENSITY			ABSOLUTE INTENSITY
Intensity	Percentage of heart rate reserve or oxygen uptake reserve	Rating of Perceived Exertion	Talk Test	MET Level
Sedentary behavior	<20*	<9	Can sing	1.0-≤1.5
Light	20-39*	9-11	Can sing	>1.5-<3.0
Moderate	40-<60	12-14	Can talk without pausing for breath, but cannot sing	3.0-<6.0
Vigorous	>60	14-17	Cannot talk without pausing for breath	≥6.0

*Information in table adapted from multiple sources, including guidelines by the American College of Sports Medicine (ACSM) (*ACSM's Guidelines for Exercise Testing and Prescription*. Eleventh Edition. Lippincott Williams & Wilkins: 2022). Note ACSM classifies >90%-100% of heart rate reserve and rating of perceived exertion levels of 18-20 as "near maximal to maximal." The table provides guidelines for individuals to characterize the intensity of physical activity.
MET = metabolic equivalents (see text for details).

TABLE 14-3 KEY PHYSICAL ACTIVITY GUIDELINES FOR ADULTS

All adults should avoid inactivity. Some physical activity is better than none, and adults who participate in any amount of physical activity gain some health benefits.

For substantial health benefits, adults should do at least 150 min (2.5 hr)/wk of moderate-intensity aerobic activity or 75 min (1.25 hr)/wk of vigorous-intensity aerobic activity, or an equivalent combination of moderate- and vigorous-intensity aerobic activity. However, recent evidence shows that bouts of exercise lasting less than 10 minutes also have health benefits.

For additional and more extensive health benefits, adults should increase their aerobic physical activity to 300 min (5 hr)/wk of moderate-intensity or 150 min (2.5 hr)/wk of vigorous-intensity aerobic physical activity, or an equivalent combination of moderate- and vigorous-intensity activity. Additional health benefits are gained by engaging in physical activity beyond this amount.

Adults should also do muscle-strengthening activities that are moderate or high intensity and involve all major muscle groups on 2 or more days/wk, as these activities provide additional health benefits.

Adapted from U.S. Department of Health and Human Services. 2018 Physical Activity Guidelines for Americans. https://health.gov/paguidelines/pdf/paguide.pdf. Washington, DC: U.S. Accessed January 4, 2022.

EPIDEMIOLOGY

Physical Activity Levels

About 50% of U.S. adults report that they meet public health guidelines (Table 14-3) for moderate-to-vigorous physical activity, about 25% report that they meet guidelines for muscle-strengthening activity, and about 25% of adults report that they meet both guidelines.[1] Among U.S. men and women ages 17 to 42 years, about 70% report adequate physical activity for military service, but only about one third are both adequately active and eligible based on their body mass index.[2] In the United States, men, White individuals, younger people, and people with greater incomes and education on average report more physical activity. Furthermore, although recreational physical activity is either stable or slightly improving, Americans have experienced a steady decline in occupational physical activity over the past five decades, and it is likely that levels of physical activity around the home have also declined.

Preventive Health Benefits in Adults

There is strong evidence that health-enhancing physical activity (Table 14-2) reduces the risk for premature mortality and coronary artery disease (Chapter 59), stroke (Chapter 376), high blood pressure (Chapter 64), adverse lipid profile (Chapter 190), type 2 diabetes mellitus (Chapter 210), metabolic syndrome, osteoporosis (Chapter 225), colon cancer (Chapter 179), breast cancer (Chapter 183), obesity (Chapter 201), and depression (Chapter 362).[3,4] The reduction in risk is substantial: for example, when active and inactive adults are compared, the risk reduction is greater than or equal to 30% for all-cause mortality, cardiovascular disease,[5] stroke, hypertension, colon cancer, and type 2 diabetes. Randomized trials show that multicomponent exercise programs, most commonly focused on balance training and muscle-strengthening activity, reduce the risk of falls and fall-related fractures by as much as 40%,[A1] and balance training likely improves physical function in older adults.[A2] Randomized trials show that exercise in older adults reduces the risk of hospitalization and mortality by 30%.[A3] Health-enhancing aerobic and muscle-strengthening activities also reduce the risk for cognitive impairment in older adults and improve cognition in adults over age 50 years,[A4] in part because levels of glycosylphosphatidylinositol, which is produced in the liver, increase with exercise and mitigate aging in the brain.[6] However, exercise does not slow cognitive decline in patients with mild to moderate dementia (Chapter 371).[A5] Some evidence also suggests that physical activity reduces the risk for anxiety disorders, osteoarthritis, sleep disorders, and back pain, as well as many types of cancer.

By some estimates, 10% or more of aggregate U.S. health care expenditures are related to inadequate physical activity. The benefits of physical activity are independent of other risk factors. For example, a sedentary obese smoker achieves health benefits from exercise, even if they continue to smoke and remain obese. When a healthy diet, regular activity, and abstinence from smoking occur together, the lifestyle effects are dramatic.

Mechanisms of Effect and Dose Response

The health benefits of physical activity are due to multiple incompletely understood physiologic effects. For example, physical activity reduces blood pressure in people with hypertension (Chapter 64).[A6] Possible mechanisms include reducing sympathetic activity and increasing vagal tone, reducing norepinephrine levels, releasing vasodilators such as endorphins, reducing insulin resistance, reducing plasma renin levels, and preventing overweight and obesity. In adults with type 2 diabetes, the effects of physical activity on skeletal muscle include changes in contractile protein isoforms, mitochondrial volume and functional capacity, metabolic regulation, intracellular signaling, and neuromuscular function.[A7]

Rather than its intensity or frequency, the dominant determinant of the health benefits of physical activity is likely the total weekly volume (amount) of moderate-to-vigorous physical activity. Substantial health benefits begin to accrue with a volume of 500 to 1000 MET-minutes/week. An adult can accumulate 500 MET-minutes by walking at 3.0 miles per hour (a 3.3-MET activity) on 3 days a week for 50 minutes (3.3 METs × 3 × 50 minutes = ≈500 MET-minutes). When measured by caloric expenditure, this volume of walking in a 75-kg (165-lb) adult expends an extra 430 kcal in addition to the 190 kcal that would have been expended at rest.

The dose-response relationship between moderate-to-vigorous physical activity volume and health benefits is curvilinear. The marginal benefit of activity at even low amounts is substantial, and the marginal benefit decreases with greater amounts of activity. Mortality risks fall by 20% with minimal activity, by 30% in people who meet the minimum recommendation of 7.5 MET hours of activity per week, and by about 40% in people who perform more than twice that amount.

The dose of moderate-to-vigorous physical activity reflects both energy expenditure (amount) and intensity. Thus, some health benefits should occur at low energy expenditure (i.e., low doses of moderate-to-vigorous physical activity) and at low intensity (i.e., light intensity). For example, 15 minutes per day (90 minutes per week) of moderate-intensity activity is associated with about a 15% decrease in mortality. Even at lower levels of moderate-to-vigorous physical activity, more energy expenditure from light-intensity activity, as indicated by less sitting time, is associated with lower mortality. However, greater amounts of moderate-to-vigorous physical activity (e.g., about 60 to 75 minutes per day) may be sufficient to eliminate the adverse effects of sitting. Muscle-strengthening activity also appears to be associated with lower risk of all-cause mortality, independent of the

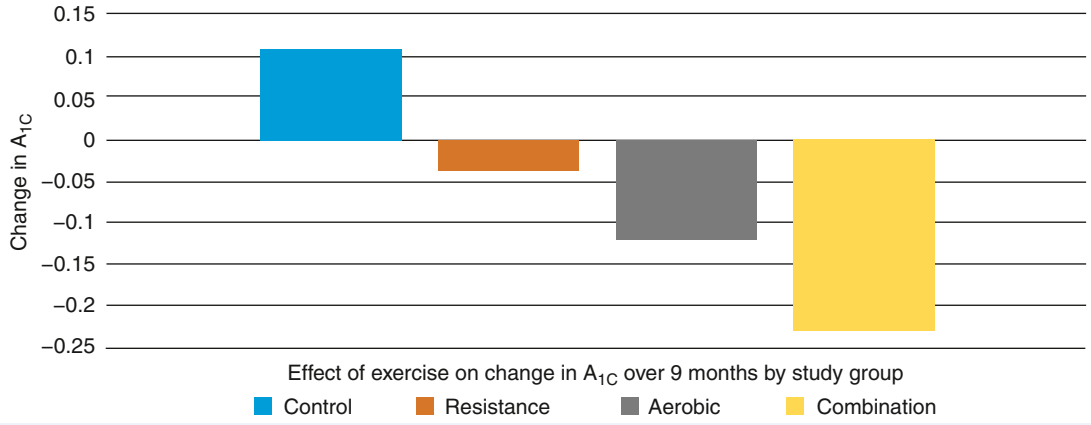

FIGURE 14-1. **Changes in hemoglobin A_{1c} levels in a 9-month randomized trial comparing three exercise interventions to a control in adults with type 2 diabetes (total N = 262). The largest improvement in A_{1c} occurred with combined aerobic exercise and resistance training (muscle-strengthening activity). (Data from Church TS, Blair SN, Cocreham S, et al. Effects of aerobic and resistance training on hemoglobin A_{1c} levels in patients with type 2 diabetes: a randomized controlled trial. *JAMA*. 2010;304:2253-2262.)**

amount of aerobic activity. Additionally, a combination of strength training and aerobic training produces greater health benefits than either alone to promote physical function in older adults, to lower hemoglobin A_{1c} levels in people with diabetes (Fig. 14-1), and to improve insulin sensitivity in adults with metabolic syndrome.

TREATMENT

Therapeutic Health Benefits in Adults

Clinical practice guidelines assign a substantial therapeutic role to physical activity in patients with coronary heart disease, high blood pressure (Chapter 64), type 2 diabetes (Chapter 210), obesity (Chapter 201), osteoporosis (Chapter 225), osteoarthritis (Chapter 241), claudication (Chapter 65), and chronic obstructive pulmonary disease (Chapter 76). Physical activity also plays a role in the management of depression and anxiety disorders (Chapter 362), elevated cholesterol levels (Chapter 190), pain (Chapter 26), heart failure (Chapter 46),[A8] syncope (Chapter 50), stroke (Chapter 375), back pain (Chapter 369), dementia (Chapter 371), and constipation (Chapter 123), as well as in the prophylaxis of venous thromboembolism (Chapter 68). Although there is more evidence for the therapeutic effects of aerobic exercise, muscle strengthening exercise also can have therapeutic effects, which can be additive or synergistic to those of aerobic exercise alone.

Health Risks of Physical Activity

Physical activity and exercise have some risks. Musculoskeletal injuries are by far the most common type of activity-related adverse event. The risk of injury depends on the type and volume of activity. The weekly volume of activity is directly related to the risk of musculoskeletal injuries, but when following public health guidelines of about 500 to 1000 MET-minutes/week, the risk of injury is low. The risk of injury is directly related to the rate of increase in the dose of activity, with more rapid increases having greater risk. Previous musculoskeletal injuries, excess weight, and low physical fitness also increase the risk of injury.

Relatively vigorous physical activity acutely increases the risk for sudden cardiac death (Chapter 50) and acute myocardial infarction (Chapter 58). However, the risk of sudden death and nonfatal events during and immediately after physical activity is extremely low—well below 1 event per 1,000,000 person-hours of activity. Importantly, physically active adults are protected from fatal and nonfatal cardiac events, with about 70% reduction in their risk of sudden death. This protection occurs because the time spent in vigorous activity per day is relatively small, so the risk of sudden cardiac death secondary to vigorous activity is far outweighed by the protective effect on cardiac events during the remainder of the day.

Recommended Amounts of Aerobic Activity for Prevention

To obtain substantial health benefits from physical activity, adults should partake in at least 150 minutes/week of moderate-intensity aerobic activity or 75 minutes/week of vigorous-intensity activity. Adults can do a combination of both moderate- and vigorous-intensity activity, using the rule of thumb that 1 vigorous-intensity minute of activity is equivalent to 2 moderate-intensity minutes.[7,8] Although previous recommendations were for bouts of aerobic activity of at least 10 minutes, bouts less than 10 minutes also appear to provide health benefits.

Recommended Amounts of Muscle-Strengthening Activity for Prevention

Adults should perform activities that strengthen the major muscle groups of the body at least 2 days each week. The major muscle groups are the legs, hips, back, chest, abdomen, shoulders, and arms.

Flexibility Activity

Flexibility activities are an important part of a complete physical activity regimen, but there is insufficient evidence that flexibility activities provide any health benefits, even for preventing injuries. Flexibility training may facilitate the types of physical activity that have health benefits. If so, flexibility training may be more important for people with reduced flexibility, such as older adults with age- and disease-related changes in range of motion.

Balance Activity

Balance training is recommended for adults at increased risk for falls, such as those older than 65 years with impaired gait or balance or frequent falls. Examples of balance exercises include sideways walking, backward walking, heel walking, and standing using a narrow base of support. Tai chi is an evidence-based approach to prevent falls. Preferably, adults at risk for falls should do balance training at least 3 days/week in the context of an evidence-based fall prevention program.

Sedentary Behavior

Increasing light-intensity activities by decreasing sedentary behavior is helpful for achieving and maintaining a healthy weight and reducing adverse health events. For example, more sedentary time is associated with greater risk of all-cause mortality, cardiovascular disease, some cancers, and type 2 diabetes.

Guidelines for Weight Management

The amount of activity required to maintain a healthy body weight varies widely among adults. For some adults, the amount of physical activity recommended in the guidelines will result in a stable, healthy body weight. Many adults, however, need greater amounts of activity to achieve a healthy weight.[9] These individuals should restrict their caloric intake and gradually increase their weekly physical activity to the point that is effective in achieving and maintaining a healthy body weight for them.

Additional Guidelines for Older Adults

In addition to balance training, older adults should be encouraged to be as active as feasible.[A9] For example, older adults who cannot do 150 minutes/week of moderate-intensity activity should be as active as their abilities and conditions allow. Resistance training and tai chi may be especially beneficial.[A10] Older adults should determine their level of physical activity using relative intensity, not absolute intensity. This latter guideline seeks to avoid inappropriately high levels of effort in older adults who have low fitness.

Recommending Physical Activity in Clinical Settings

Promoting physical activity in clinical settings involves essentially the same steps as the "5 A's" of smoking cessation (Chapter 363): ask, advise, assess, assist, arrange. Consistent with this approach, physicians should be knowledgeable in four domains: how to assess physical activity; how to make safe recommendations/prescriptions for physical activity in both healthy people and people with chronic conditions[10]; how to use effective behavioral interventions; and how to engage in their own active lifestyle for professional balance and as role models for patients.

Health care providers should ask and advise patients about physical activity regularly.[A11,11] One quality-of-care measure assesses whether asking and advising are done at least once a year in older adults. Some recommend that physical activity should be a "vital sign" that is assessed at every visit. Adults—especially older adults—identify their health care providers as an important source of advice on physical activity. Behavioral counseling is recommended for adults even if they have no cardiovascular risk factors. Intensive behavioral counseling is recommended for adults who are overweight or obese and have additional risk factors for cardiovascular disease. Such counseling should be a component

of community programs that promote physical activity in people at increased risk for type 2 diabetes.

Lifestyle Prescription

A lifestyle prescription refers to approaches that integrate physical activity into daily life. For example, rather than walking specifically for exercise, a person walks to work or walks for pleasure as a recreational activity. Common ways to integrate physical activity into daily life are walking and biking for transportation, performing yard work, and gardening. Use of wearable devices such as pedometers to track physical activity can increase steps per day by about 2000 above baseline and increase adherence to lifestyle prescriptions. More total steps per day are associated with lower all-cause mortality, whereas step intensity is not, after controlling for total steps.[12]

Tailoring the Recommendation

Recommendations should be tailored to individual abilities, individual preferences, medical conditions, and behavior techniques that improve adherence. Interventions are more likely to be successful if they include mutual goal setting, regular feedback, graded tasks, and use of equipment, such as a step monitor.[A12] Most people prefer home-based programs, which can provide health benefits that are similar to those of programs conducted elsewhere.[A13]

A target level of physical activity below that of preventive recommendations is appropriate for adults who have very low physical fitness, a large burden of chronic disease (e.g., severe chronic obstructive lung disease), or major functional limitations. An assessment of the nature of the activity limitation and the individual's capabilities and preferences can determine the target activity level and other details of the activity recommendation. Often, promoting physical activity in such adults relies on health care and community resources designed for people with preexisting limitations, such as cardiac rehabilitation, pulmonary rehabilitation, and exercise classes for adults with arthritis.

Risk Management

Strategies to reduce injury during physical activity include increasing physical activity gradually over time, selecting activities in which collision or contact with people or objects is unusual, increasing physical fitness, using appropriate gear and sports equipment (e.g., bike helmets), engaging in activities in safe environments, and following basic safety rules and policies. Popular activities such as walking, biking, swimming, and gardening have a low risk of injury. When individuals are increasing their level of physical activity, they should start with relatively moderate-intensity activity, increase the duration and frequency first, and then the intensity later. In general, adding 5 to 15 minutes of moderate-intensity activity per session, two to three times a week, to a person's usual activities carries a low risk of musculoskeletal injury and no known risk of sudden cardiac death.

There is no evidence of any protective value for medical consultation or of supervised exercise in healthy people of any age who seek to increase their level of physical activity. The U.S. Preventive Services Task Force recommends against routine screening for coronary disease in adults at low risk. Even in adults who are at high risk for coronary disease, there is insufficient evidence to recommend for or against screening with resting electrocardiography, exercise treadmill testing, electron-beam computed tomography, or C-reactive protein concentrations.

Coordination between Medical Care and the Community

Many factors that affect physical activity levels in Americans, such as the characteristics of the communal environment (e.g., parks and recreational facilities) and the social environment (e.g., crime and social support), are difficult to influence in medical care settings. Community-level interventions that address such characteristics are essential to promoting physical activity. Effective community-based interventions include school physical education, social support interventions, community-wide campaigns, and enhancement of access to places where physical activity is possible. Medical care and community efforts should be synergistic and mutually supportive. For example, health plans should advocate for evidence-based community interventions. Community programs should serve as resources for evidence-based therapeutic activity for selected chronically ill adults, such as exercise classes designed to reduce the risk of falls.

15 IMMUNIZATION

ANDREW T. KROGER AND WALTER A. ORENSTEIN

GENERAL CHARACTERISTICS OF IMMUNIZATIONS

Immunization protects against disease or the sequelae of disease through the administration of an immunobiologic—a vaccine, toxoid, immune globulin preparation, or antitoxin. Protection induced by immunization can be active or passive (Tables 15-1 and 15-2).

ACTIVE IMMUNIZATION

Administration of a vaccine or toxoid causes the body to produce an immune response against the infectious agent or its toxins. Active immunization generally results in long-term immunity, although the onset of protection may be delayed because it takes time for the body to respond. Vaccines consist of suspensions of live (usually attenuated) microbes, nonlive microbes, or proteins of microbes. Nonlive recombinant vaccines[1] are genetically engineered, so they cannot be considered inactivated because they never consisted of whole microbes. By comparison, nonlive vaccines that are not produced via genetic engineering retain the characterization "inactivated." Toxoids are modified bacterial toxins that retain immunogenic properties but lack toxicity. With live attenuated vaccines, small quantities of living organisms multiply within the recipient until an immune response cuts off replication. In most recipients, a single dose of most live vaccines generally induces a long-term immune response that closely parallels natural infection. Additional doses are recommended to ensure high rates of population immunity.

PASSIVE IMMUNIZATION

Passive immunization using immune globulins or antitoxins delivers preformed antibodies to provide rapid temporary immunity. Immune globulins obtained from human blood may contain antibodies to a variety of agents, depending on the pool of human plasma from which they are prepared. Specific immune globulins are made from the plasma of donors with high levels of antibodies to

of community programs that promote physical activity in people at increased risk for type 2 diabetes.

Lifestyle Prescription

A lifestyle prescription refers to approaches that integrate physical activity into daily life. For example, rather than walking specifically for exercise, a person walks to work or walks for pleasure as a recreational activity. Common ways to integrate physical activity into daily life are walking and biking for transportation, performing yard work, and gardening. Use of wearable devices such as pedometers to track physical activity can increase steps per day by about 2000 above baseline and increase adherence to lifestyle prescriptions. More total steps per day are associated with lower all-cause mortality, whereas step intensity is not, after controlling for total steps.[12]

Tailoring the Recommendation

Recommendations should be tailored to individual abilities, individual preferences, medical conditions, and behavior techniques that improve adherence. Interventions are more likely to be successful if they include mutual goal setting, regular feedback, graded tasks, and use of equipment, such as a step monitor.[A12] Most people prefer home-based programs, which can provide health benefits that are similar to those of programs conducted elsewhere.[A13]

A target level of physical activity below that of preventive recommendations is appropriate for adults who have very low physical fitness, a large burden of chronic disease (e.g., severe chronic obstructive lung disease), or major functional limitations. An assessment of the nature of the activity limitation and the individual's capabilities and preferences can determine the target activity level and other details of the activity recommendation. Often, promoting physical activity in such adults relies on health care and community resources designed for people with preexisting limitations, such as cardiac rehabilitation, pulmonary rehabilitation, and exercise classes for adults with arthritis.

Risk Management

Strategies to reduce injury during physical activity include increasing physical activity gradually over time, selecting activities in which collision or contact with people or objects is unusual, increasing physical fitness, using appropriate gear and sports equipment (e.g., bike helmets), engaging in activities in safe environments, and following basic safety rules and policies. Popular activities such as walking, biking, swimming, and gardening have a low risk of injury. When individuals are increasing their level of physical activity, they should start with relatively moderate-intensity activity, increase the duration and frequency first, and then the intensity later. In general, adding 5 to 15 minutes of moderate-intensity activity per session, two to three times a week, to a person's usual activities carries a low risk of musculoskeletal injury and no known risk of sudden cardiac death.

There is no evidence of any protective value for medical consultation or of supervised exercise in healthy people of any age who seek to increase their level of physical activity. The U.S. Preventive Services Task Force recommends against routine screening for coronary disease in adults at low risk. Even in adults who are at high risk for coronary disease, there is insufficient evidence to recommend for or against screening with resting electrocardiography, exercise treadmill testing, electron-beam computed tomography, or C-reactive protein concentrations.

Coordination between Medical Care and the Community

Many factors that affect physical activity levels in Americans, such as the characteristics of the communal environment (e.g., parks and recreational facilities) and the social environment (e.g., crime and social support), are difficult to influence in medical care settings. Community-level interventions that address such characteristics are essential to promoting physical activity. Effective community-based interventions include school physical education, social support interventions, community-wide campaigns, and enhancement of access to places where physical activity is possible. Medical care and community efforts should be synergistic and mutually supportive. For example, health plans should advocate for evidence-based community interventions. Community programs should serve as resources for evidence-based therapeutic activity for selected chronically ill adults, such as exercise classes designed to reduce the risk of falls.

ABSTRACT

Immunization is one of the most cost-effective methods of preventing morbidity and mortality from infectious diseases. In the United States, routine immunization, particularly of children, has resulted in decreases of 90% or more in reported cases of measles, mumps, rubella, congenital rubella syndrome, poliomyelitis, tetanus, invasive *Haemophilus influenzae* type b, varicella, hepatitis A, diphtheria, and pertussis. In many circumstances, immunization in children and adults not only prevents morbidity and mortality but also reduces long-term health care costs.

TABLE 15-1 PASSIVE IMMUNIZATIONS FOR ADULTS

DISEASE	NAME OF MATERIAL*†§	COMMENTS AND USE
Acquired immunodeficiency syndrome (AIDS)	Immune globulin intravenous (IGIV)	To prevent bacterial infection
Botulism	For non-infant botulism: in the United States, equine botulism antitoxin (BAT) against toxin types A, B, C, D, E, F, G For infant botulism: in the United States, botulism immune globulin types A and B; BabyBIG	Equine heptavalent antitoxin for treatment of non-infant botulism; available from CDC through state or local health department—contact emergency number of local or state health department. Human immune globulin for treatment of infant botulism available from the California Department of Health, Infant Botulism Treatment and Prevention Program, (510)231-7600
Chronic immune demyelinating polyneuropathy (CIDP)	Immune globulin intravenous (IGIV)	To improve neuromuscular ability
Chronic lymphocytic leukemia (CLL)	Immune globulin intravenous (IGIV)	To prevent bacterial infection
Cytomegalovirus	Cytomegalovirus immune globulin intravenous	Prophylaxis for bone marrow and kidney transplant recipients
Digoxin intoxication	Digoxin immune Fab, ovine	
Diphtheria	Diphtheria antitoxin, equine	Treatment of established disease; allergic reactions possible to serum of equine origin, available only from CDC
Erythroblastosis fetalis	Rho (D) immune globulin, intramuscular Rho (D) immune globulin, intravenous	Rh-negative women who are pregnant with Rh-positive infants
Hepatitis A	Immune globulin, intramuscular (IGIM)	Preexposure and postexposure prophylaxis for travelers and others who need protection before immunity can be achieved with hepatitis A vaccination
Hepatitis B	Hepatitis B immune globulin	Prophylaxis for needle stick or mucous membrane contact with HBsAg-positive persons, for sexual partners with acute hepatitis B or carriers of hepatitis B, for infants born to mothers who are carriers of HBsAg, for infants whose mother or primary caregiver has acute hepatitis B
Hypogammaglobulinemia	Immune globulin, intravenous, subcutaneous, intramuscular	Maintenance therapy
Idiopathic thrombocytopenic purpura	Immune globulin, intravenous (IGIV)	Therapy for acute episodes
Measles	Immune globulin, intramuscular (IGIM) Immune globulin, intravenous (IGIV)	Prevention or modification of disease in exposed persons, not for control of outbreaks; particularly indicated for unvaccinated infants aged <6 months, pregnant persons without evidence of measles immunity, and severely immunocompromised persons
Multifocal motor neuropathy	Immune globulin intravenous (IGIV)	To improve muscle strength
Rabies	Rabies immune globulin	Postexposure prophylaxis of animal bites
Scorpion sting	Centruroides (scorpion) immune F(ab')2, equine	Specific for *Centruroides* genus scorpions (e.g., Arizona bark scorpion)
Snakebite, coral snake	Antivenin (*Micrurus fulvius*), equine; North American coral snake antivenin	Specific for North American coral snake, *Micrurus fulvius*
Snakebite, crotalidae	Antivenin (Crotalidae) polyvalent, equine Crotalidae immune F(ab')2, equine	Effective for viper and pit viper bites, including rattlesnakes, copperheads, moccasins
Spider bite, black widow	Antivenin (*Lactrodectus mactans*), equine	Specific for black widow spider, *Latrodectus mactans*, and other members of the genus
Tetanus	Tetanus immune globulin	Management of tetanus-prone wounds in persons without adequate prior active immunization and treatment of tetanus
Vaccinia	Vaccinia immune globulin, intravenous (IGIV)	Treatment of eczema vaccinatum, vaccinia necrosum, and severe inadvertent inoculations such as ocular vaccinia after vaccinia (smallpox) vaccination; available only from CDC
Varicella	Varicella-zoster immune globulin	Prevention or modification of disease in exposed persons. Indicated for persons who are at high risk for complications from varicella, who have not had varicella or varicella vaccine, and who are exposed to varicella or herpes zoster: immunocompromised persons, newborn infants whose mothers have varicella around the time of delivery (i.e., 5 days before to 2 days after), hospitalized premature infants born at ≥28 weeks of gestation whose mothers do not have evidence of immunity to varicella, hospitalized premature infants born at <28 weeks of gestation or who weigh ≤1,000 g at birth, regardless of their mothers' evidence of immunity to varicella, pregnant persons; should be given as soon as possible after exposure and within 10 days

*All products to be administered intramuscularly, unless otherwise indicated.
†All products derived from humans unless otherwise specified.

TABLE 15-2 SELECTED IMMUNIZING AGENTS INDICATED FOR ADULTS*

DISEASE	IMMUNIZING AGENT	INDICATIONS	SCHEDULE	MAJOR CONTRAINDICATIONS (C) AND PRECAUTIONS (P)	COMMENTS
Adenovirus	Adenovirus type 4 and type 7 live oral vaccine	Military: for prevention of febrile acute respiratory disease caused by type 4 and type 7 adenovirus	One oral dose (two tablets)	C: Pregnancy C: Severe allergic reaction (e.g., anaphylaxis) to a vaccine component C: Inability to swallow whole tablets without chewing P: Altered immunocompetence P: Moderate or severe acute illness	Avoid pregnancy for 6 weeks after vaccination Virus may be shed in stool: exercise caution for 28 days after vaccination in contact with children younger than 7 years, pregnant persons, or immunosuppressed persons
Anthrax	Anthrax vaccine, adsorbed, inactivated vaccine	Preexposure prophylaxis of persons at high risk of exposure (e.g., military, certain laboratory workers) Consider with antibiotics for postexposure prophylaxis	0.5-mL dose IM at 0, 4, and 6 weeks and boosters at 12 and 18 months, then booster every 3 years thereafter If used after exposure, three doses at 0, 2, and 4 weeks with 60 days of antimicrobial therapy; antibiotics should be continued for 14 days after third dose	C: Severe allergic reaction to a vaccine component or after a prior dose P: Moderate or severe acute illness	Effectiveness against aerosol exposure inferred primarily from animal data A dose-sparing schedule of two doses with 2-4 week interval exists if there is a supply shortage
Cholera	Cholera vaccine, live attenuated oral cholera vaccine		One 100-mL oral dose before travel; booster doses are not presently recommended	C: Severe allergic reaction to a vaccine component or after a prior dose P: Moderate or severe acute illness Limited or lack of data on use of vaccine in: • Pregnant persons • Immunocompromised persons • Children <18 yr and adults 65 yr and older	All travelers to cholera-affected areas should follow safe food and water precautions and proper sanitation and personal hygiene measures as primary strategies to prevent cholera
COVID-19 (three types of vaccines)	1. mRNA vaccine (non-live messenger RNA encoding the novel SARS-2 coronavirus [NCoV2] spike protein)	Pfizer-BioNTech COVID-19 vaccine: authorized for ages 6 months through 11 years and approved for ages 12 years and older Moderna COVID-19 vaccine approved for ages 18 years and older	The information in this row/column is current for ADULTS only: Two brands (no preference) BNT162b2 two 0.3-mL doses separated by 3-8 weeks mRNA-1273 two 0.5-mL doses separated by 4-8 weeks A third dose of mRNA vaccine is recommended 28 days after the primary series for persons ages 5 years and older who are immunosuppressed. A booster dose of mRNA vaccine is recommended at least 2 months after the primary series for persons ages 12 years or older. The dose must be Pfizer-BioNTech for persons 12 years through 17 years of age. A booster dose is also recommended for persons ages 12 years old and older who were immunosuppressed upon receipt of the primary series and received an additional dose. The booster dose should be administered at least 2 months after the additional dose	C: History of severe allergic reaction to a prior dose of vaccine C: History of a known allergy to a component of the COVID-19 vaccine P: History of an immediate allergic reaction to any vaccine other than COVID-19 vaccine or to any injectable therapy (i.e., intramuscular, intravenous, or subcutaneous vaccines or therapies [excluding subcutaneous immunotherapy for allergies, i.e., "allergy shots"]) P: A history of a nonsevere, immediate (onset less than 4 hours) allergic reaction after a dose of one type of COVID-19 vaccine (i.e., mRNA or Janssen) is a precaution only to like-type vaccine (i.e., if the history is to an mRNA vaccine, this precaution is to any mRNA vaccine; if the history is to a COVID-19 vector vaccine, this precaution is to any COVID-19 vector vaccine) P: An allergy-related contraindication to one type of a COVID-19 vaccine is a precaution to other-type COVID-19 vaccine (i.e., if the contraindication is to mRNA vaccine, the precaution is to any COVID-19 vector vaccine; if the contraindication is to COVID-19 vector vaccine, the precaution is to any mRNA vaccine) P: History of myocarditis or pericarditis after a dose of an mRNA or Novavax COVID-19 vaccine P: Moderate or severe acute illness P: History of multisystem inflammatory syndrome	If a precaution on the basis of allergy, observe patient for 30 minutes instead of just 15 minutes Increased risk (3.5 cases per 1 million doses) of myocarditis and pericarditis. The highest risk is in males ages 12 years to 29 years

TABLE 15-2 SELECTED IMMUNIZING AGENTS INDICATED FOR ADULTS*—cont'd

DISEASE	IMMUNIZING AGENT	INDICATIONS	SCHEDULE	MAJOR CONTRAINDICATIONS (C) AND PRECAUTIONS (P)	COMMENTS
	2. Non-replicating adenovirus vector vaccine	Not licensed: Emergency Use Authorization Only: 18 years of age and older	One 0.5-mL dose	C: History of severe allergic reaction to a prior dose of vaccine C: History of a diagnosed allergy to a component of the COVID-19 vaccine C: Thrombosis with thrombocytopenia following receipt of a previous Janssen COVID-19 vaccine (or other COVID-19 vaccines not currently authorized in the United States that are based on adenovirus vectors, e.g., AstraZeneca) is a contraindication for Janssen COVID-19 only P: History of an immediate allergic reaction to any vaccine other than COVID-19 vaccine or to any injectable therapy (i.e., intramuscular, intravenous, or subcutaneous vaccines or therapies [excluding subcutaneous immunotherapy for allergies, i.e., "allergy shots"]) P: A history of a nonsevere, immediate (onset less than 4 hours) allergic reaction after a dose of one type of COVID-19 vaccine (i.e., mRNA or Janssen) is a precaution only to like-type vaccine (i.e. if the history is to an mRNA vaccine the precaution is to any mRNA vaccine; if the history is to a COVID-19 vector vaccine, the precaution is to any COVID-19 vector vaccine) P: An allergy-related contraindication to one type of a COVID-19 vaccine is a precaution to other-type COVID-19 vaccine (i.e., if the contraindication is to mRNA vaccine, the precaution is to any COVID-19 vector vaccine; if the contraindication is to COVID-19 vector vaccine, the precaution is to any mRNA vaccine) P: History of Guillain-Barré syndrome within 6 weeks of Janssen COVID-19 vaccine P: Moderate or severe acute illness	If a precaution on the basis of allergy, observe patient for 30 minutes instead of just 15 minutes Increased risk (7 cases in 1 million doses in persons ages 18 years to 49 years, and 1 case per million doses in persons age 50 years and older) of thrombosis with thrombocytopenia. An increased risk is in females age 18 to 49 years Increased risk (7.8 cases per million doses) of Guillain-Barré syndrome, especially in males ages 50 to 64 years

TABLE 15-2 SELECTED IMMUNIZING AGENTS INDICATED FOR ADULTS*—cont'd

DISEASE	IMMUNIZING AGENT	INDICATIONS	SCHEDULE	MAJOR CONTRAINDICATIONS (C) AND PRECAUTIONS (P)	COMMENTS
	3. Protein subunit vaccine	Novavax COVID-19 vaccine authorized for 12 years and older	NVX-CoV2373 two 0.5-mL doses separated by 3-8 weeks. A booster is recommended at least 2 months after the primary series (preferentially the booster dose should be an mRNA vaccine)	C: History of severe allergic reaction to a prior dose of vaccine C: History of a known allergy to a component of the COVID-19 vaccine P: History of an immediate allergic reaction to any vaccine other than COVID-19 vaccine or to any injectable therapy (i.e., intramuscular, intravenous, or subcutaneous vaccines or therapies [excluding subcutaneous immunotherapy for allergies, i.e., "allergy shots"]) P: A history of a nonsevere, immediate (onset less than 4 hours) allergic reaction after a dose of one type of COVID-19 vaccine (i.e., mRNA or Janssen) is a precaution only to like-type vaccine (i.e., if the history is to an mRNA vaccine, this precaution is to any mRNA vaccine; if the history is to a COVID-19 vector vaccine, this precaution is to any COVID-19 vector vaccine). Note that Janssen and Novavax vaccines contain polysorbate. mRNA vaccines do not contain polysorbate P: An allergy-related contraindication to one type of a COVID-19 vaccine is a precaution to other-type COVID-19 vaccine (i.e., if the contraindication is to mRNA vaccine, the precaution is to any COVID-19 vector vaccine; if the contraindication is to COVID-19 vector vaccine, the precaution is to any mRNA vaccine). Note that Janssen and Novavax vaccines contain polysorbate. mRNA vaccines do not contain polysorbate P: History of myocarditis or pericarditis after a dose of an mRNA or Novavax COVID-19 vaccine P: Moderate or severe acute illness P: History of multisystem inflammatory syndrome	

TABLE 15-2 SELECTED IMMUNIZING AGENTS INDICATED FOR ADULTS*—cont'd

DISEASE	IMMUNIZING AGENT	INDICATIONS	SCHEDULE	MAJOR CONTRAINDICATIONS (C) AND PRECAUTIONS (P)	COMMENTS
Diphtheria	Tetanus and diphtheria toxoids combined Adult preparation of pertussis antigens combined with tetanus and diphtheria toxoids (Tdap)	All adults	For incompletely immunized adults, three total 0.5-mL doses IM needed for primary series: two doses IM 4 weeks apart, third dose 6-12 months after second dose; it is preferable that the first dose is Tdap, subsequent doses can be Tdap or Td Booster (Tdap or Td) every 10 years No need to repeat if schedule is interrupted	C: History of neurologic reaction after a previous dose (Tdap only) C: Severe allergic reaction to a vaccine component or after a prior dose P: Moderate or severe acute illness	Tetanus and diphtheria toxoids combined with acellular pertussis vaccine (Tdap) preferred as one-time booster for all persons who have not previously received Tdap
Ebola	Live, recombinant viral vector vaccine: backbone: vesicular stomatitis virus (VSV), with gene encoding for envelope glycoprotein of *Z. ebolavirus*	Responders to an outbreak of Ebola In United States, health care workers in federally designated Ebola Treatment Centers or other staff working in biosafety level 4 facilities	One 1-mL dose	C: Hypersensitivity or allergy to a vaccine component P: Moderate or severe acute illness	Avoid kissing or sharing razors, eating utensils, toothbrushes, drinking cups, or needles for 2 weeks Avoid donating blood or contact with high-risk persons, or exposure of livestock to blood or body fluids for 6 weeks Use barrier methods for sexual interaction for 2 months
Haemophilus influenzae type b	Hib conjugate vaccines	Adults who have anatomic or functional asplenia and who are vaccine naïve or hematopoietic cell transplant recipients	Adults who have functional and anatomic asplenia and who are vaccine naïve: 1 dose Adults who have received a hematopoietic cell transplant: 3 doses at 1-month intervals	C: Severe allergic reaction to a vaccine component or after a prior dose P: Moderate or severe acute illness	
Hepatitis A	Inactivated hepatitis A vaccine	Travelers to highly or intermediately endemic countries Men who have sex with men Persons who use illegal drugs (injection and noninjection) Persons who work with hepatitis A virus–infected primates or who do research with the virus Persons with chronic liver disease Homeless persons HIV-infected persons	Two 0.5-mL doses at least 6 months apart for persons aged ≥1 year	C: Severe allergic reaction to a vaccine component or after a prior dose P: Moderate or severe acute illness	Should be considered for outbreak control Should be administered to all adults in settings where patients with indications are seen Adults with HIV can be tested at least 1 month after receipt of HepA vaccine to confirm immunity. If negative, a revaccination dose can be considered.

TABLE 15-2 SELECTED IMMUNIZING AGENTS INDICATED FOR ADULTS*—cont'd

DISEASE	IMMUNIZING AGENT	INDICATIONS	SCHEDULE	MAJOR CONTRAINDICATIONS (C) AND PRECAUTIONS (P)	COMMENTS
Hepatitis B	Three inactivated hepatitis B virus subunit vaccines containing HBsAg; one vaccine containing HBsAg and a CpG 1018 adjuvant	All adults ages 18 through 59 years Adults ages 60 years and older with any of the following health conditions: 1. Health care and public safety workers potentially exposed to blood 2. Clients and staff of institutions for the developmentally disabled 3. Hemodialysis patients 4. Men who have sex with men 5. Users of illicit injectable drugs 6. Recipients of clotting factors 7. Household and sexual contacts of HBV carriers 8. Inmates of long-term correctional facilities 9. Persons treated for sexually transmitted diseases or with multiple sexual partners 10. Travelers with close contact for ≥6 months with populations with high prevalence of HBV carriage 11. Persons with chronic liver disease 12. HIV-infected persons 13. Persons with diabetes mellitus 14. Incarcerated persons	Vaccine without CpG adjuvant: three doses IM at 0, 1, and 6 months volume of dose (Recombivax-HB and Engerix-B, 18- to 19-year-olds: 0.5 mL; 20-year-olds and older: 1 mL; PreHevbrio: 18-year-olds and older: 1 mL) Vaccine with CpG adjuvant: two 0.5-mL doses 1 month apart	C: Severe allergic reaction to a vaccine component or after a prior dose C: Hypersensitivity to yeast P: Moderate or severe acute illness	Pregnancy is not a contraindication Health care workers who have contact with patients or blood, sexual contacts of persons with chronic HBV infection, hemodialysis patients, and other immunosuppressed persons should be tested 1-2 months after vaccination to determine serologic response Consider vaccination in any adult age 60 years and older
Herpes zoster	Recombinant zoster vaccine (RZV), a subunit vaccine containing varicella-zoster virus glycoprotein E	All adults age 50 years and older Immunocompromised adults ages 19 through 49 years of age	Two 0.5-mL doses IM 2-6 months apart	C: Allergy to vaccine components P: Moderate or severe acute illness P: Active zoster disease	
Human papillomavirus (HPV)	Noninfectious recombinant vaccine prepared from purified virus-like particles of L1 capsid proteins of HPV types 6, 11, 16, 18, 31, 33, 45, 52, and 58 (nine-valent; bivalent and quadrivalent vaccines, while licensed, are no longer available in the United States)	Routine vaccination of adolescents with catch-up vaccination for adults through age 26 years. Shared clinical decision-making regarding HPV vaccination is recommended for some adults ages 27 through 45 years	Two 0.5-mL doses IM at 0 and 6-12 months if the first dose was administered before the 15th birthday Three 0.5-mL doses IM at 0, 1 to 2, and 6 months if first dose was administered at age 15 years or older Three 0.5-mL doses IM at 0, 1 to 2, and 6 months for persons who are immunocompromised, have an autoimmune disease, or have a malignant neoplasm, regardless of age at first dose	C: Severe allergic reaction to a vaccine component or to a prior dose P: Moderate or severe acute illness	The vaccine will not protect against existing infections Because vaccines do not protect against all HPV types, screening for cervical cancer among vaccinated persons should occur as for unvaccinated persons

TABLE 15-2 SELECTED IMMUNIZING AGENTS INDICATED FOR ADULTS*—cont'd

DISEASE	IMMUNIZING AGENT	INDICATIONS	SCHEDULE	MAJOR CONTRAINDICATIONS (C) AND PRECAUTIONS (P)	COMMENTS
Influenza (three types of vaccines: inactivated virus vaccine [IIV] exists as high-dose influenza vaccine, adjuvanted influenza vaccine, and standard-dose influenza vaccine)	Inactivated virus vaccine (IIV)	All adults, with greatest priority for those at higher risk for influenza complications (e.g., ≥50 years old, persons with underlying medical conditions, pregnant persons) or in contact with those at higher risk (e.g., health care workers, and persons with close contact with children <5 years)	Annual vaccination; see annual ACIP recommendation The volume of the dose varies by brand and age: 0.5 mL or 0.7 mL	C: Severe allergic reaction to an influenza vaccine component (except eggs) or after a prior dose P: Moderate or severe acute illness P: Guillain-Barré syndrome within 6 weeks of prior dose of influenza vaccine	Optimum timing of vaccination for most people is by the end of October. However, vaccination can occur throughout the influenza season, particularly for persons at high risk for complications and their contacts who were not vaccinated earlier. Only one dose of influenza vaccine per season is recommended for adults
	Live attenuated influenza virus (LAIV)	Adults through 49 years of age	Administered intranasally (0.2 mL) See annual ACIP recommendations	C: Persons <2 years or ≥50 years C: Pregnant persons C: Hypersensitivity to components of vaccine (except eggs) C: Anatomic or functional asplenia (including sickle cell disease) C: Cochlear implant C: Cerebrospinal fluid (CSF) leak C: Use of influenza antivirals C: Use of high-dose aspirin or high-dose aspirin-containing therapy C: Close contacts or a caregiver of someone with severe immunocompromise (requiring a protective environment) P: Persons with underlying disorders that place them at high risk of influenza complications (including asthma) P: Have history of Guillain-Barré syndrome within 6 weeks of prior dose of influenza vaccine P: Moderate or severe acute illness	Can be used for household contacts and health care workers caring for immunocompromised patients if the patient does not require a protected environment
	Recombinant influenza vaccine (RIV)	Adults	Annual vaccination (one 0.5-mL dose)	C: Severe allergic reaction to any component of the vaccine P: Moderate or severe acute illness P: Guillain-Barré syndrome within 6 weeks of prior dose of influenza vaccine	
Japanese encephalitis	Inactivated Japanese encephalitis virus vaccine	Travelers to Asia spending at least 1 month in endemic areas during transmission season	Two 0.5-mL doses IM on days 0 and 28. The FDA approved an alternate 0- and 7-day schedule	C: Pregnancy P: Moderate or severe acute illness	
Measles	Live virus vaccine (with mumps and rubella [MMR])	All adults born after 1956 without history of live vaccine on or after first birthday, laboratory confirmation of disease, or detectable measles antibody Persons born before 1957 generally can be considered immune	One 0.5-mL dose sufficient for most adults; two doses at least 1 month apart indicated for persons entering college or medical facility employment, traveling abroad, or at risk of measles during outbreaks	C: Altered immunity (e.g., leukemia, lymphoma, generalized malignant disease, congenital immunodeficiency, immunosuppressive therapy) C: Anaphylactic hypersensitivity to neomycin or gelatin C: Pregnancy P: Thrombocytopenia P: Immune globulin or other blood products within prior 3-11 months P: Untreated tuberculosis P: Moderate or severe acute illness	Persons with anaphylactic allergies to eggs may be vaccinated (see text) Vaccine should be administered to persons with asymptomatic HIV infection and should be considered for other patients with HIV infection except those with severe immunocompromise

TABLE 15-2 SELECTED IMMUNIZING AGENTS INDICATED FOR ADULTS*—cont'd

DISEASE	IMMUNIZING AGENT	INDICATIONS	SCHEDULE	MAJOR CONTRAINDICATIONS (C) AND PRECAUTIONS (P)	COMMENTS
Meningococcal disease (two types of vaccines)	1. Meningococcal conjugate vaccines containing polysaccharide of serogroups A, C, W, and Y	All persons with persistent complement component deficiencies or complement inhibitor use, HIV infection, or anatomic or functional asplenia Persons who will travel to areas where meningococcal infection is hyperendemic or epidemic Microbiologists routinely exposed to *Neisseria meningitidis* People at increased risk during an outbreak (e.g., unvaccinated or undervaccinated first-year college students living in residence halls, military recruits) Other persons at risk during an outbreak	A two-dose primary series recommended for individuals with complement component deficiency or complement inhibitor use, HIV infection, or anatomic or functional asplenia; others should receive a single dose Individuals at ongoing increased risk of meningococcal disease should receive a booster dose every 5 years	C: Allergic reactions to a component of the vaccine, including diphtheria or tetanus toxoid, or to other diphtheria toxoid-, CRM197-, or tetanus-toxoid-containing vaccines (depending on vaccine) P: Moderate or severe acute illness	
	2. Recombinant meningococcal B protein vaccines containing either two alleles of one protein (MenB-FHbp) or three proteins as well as one protein-containing outer membrane vesicle (MenB-4 C) (ages 10 years and older)	All persons with persistent complement component deficiencies or complement inhibitor use or anatomic or functional asplenia Certain laboratory workers May be useful during localized outbreaks May be administered to young adults before age 24 years to provide short-term protection against most strains of serogroup B meningococcal disease	For healthy persons who are not at increased risk for meningococcal disease, either a 2-dose series of MenB-4C at 0 and 1 mo, or a 2-dose series of MenB-FHbp at 0 and 6 months (each dose 0.5 mL). For persons at increased risk for meningococcal disease, including during serogroup B outbreaks, MenB-FHbp should be given as a 3-dose series at 0, 1-2, and 6 months. For persons at increased risk, the 2-dose series of MenB-4C at 0 and 1 month remains in effect. The same vaccine product should be used for all doses Booster dose is recommended 1 year after the primary series and every 2-3 years thereafter for those who continue to be at increased risk Booster dose is indicated in an outbreak of serogroup B disease if 6 months or more have passed since completion of the primary series	C: Severe allergic reaction to a vaccine component or after a prior dose P: Latex sensitivity (MenB-4C only) P: Moderate or severe acute illness P: Pregnancy	Evidence supports use of MenB vaccines in all persons at increased risk for serogroup B meningococcal disease Shared clinical decision making for young adults not at increased risk
Mumps	Live virus vaccine (measles and rubella [MMR])	All adults born after 1956 without history of live vaccine on or after first birthday, laboratory confirmation of disease, or detectable mumps antibody Persons born before 1957 generally can be considered immune	One 0.5-mL dose sufficient for most adults Two doses at least 1 month apart indicated for persons entering college or medical facility employment or traveling abroad, or at risk of mumps during outbreaks	C: Altered immunity (e.g., leukemia, lymphoma, generalized malignant disease, congenital immunodeficiency, immunosuppressive therapy) C: Anaphylactic hypersensitivity to neomycin or gelatin C: Pregnancy P: Immune globulin or other blood products within prior 3 to 11 months P: Thrombocytopenia if administered with measles vaccine P: Moderate or severe acute illness	Persons with anaphylactic allergies to eggs may be vaccinated Persons previously vaccinated with two doses of a mumps-containing vaccine who are identified by public health as at increased risk for mumps because of a mumps outbreak should receive a third dose of a mumps-containing vaccine to improve protection against mumps disease and related complications

TABLE 15-2 SELECTED IMMUNIZING AGENTS INDICATED FOR ADULTS*—cont'd

DISEASE	IMMUNIZING AGENT	INDICATIONS	SCHEDULE	MAJOR CONTRAINDICATIONS (C) AND PRECAUTIONS (P)	COMMENTS
Pertussis	Adult preparation of pertussis antigens combined with tetanus and diphtheria toxoids (Tdap)	Catch-up vaccination for all persons ≥13 years May be given whenever tetanus-toxoid–containing vaccine is indicated One dose per pregnancy	One 0.5-mL dose Pregnant persons: one dose during each pregnancy preferably early in the period between 27 and 36 weeks of gestation	C: History of neurologic reaction after a previous dose (Tdap only) C: Severe allergic reaction to a vaccine component or after a prior dose P: Moderate or severe acute illness	Two preparations are available, one licensed for all persons ≥10 yr, one for 10 to 64 yr olds
Pneumococcal disease (three vaccines)	15-valent pneumococcal conjugate vaccine (PCV15) 23-valent pneumococcal polysaccharide vaccine (PPSV23) 20-valent pneumococcal conjugate vaccine (PCV20)	All adults age 65 years or older and adults ages 19 to 64 years at risk for invasive pneumococcal disease (including asthma), diabetes mellitus, alcohol use disorder, cirrhosis, cerebrospinal fluid leaks, splenic dysfunction or anatomic asplenia, Hodgkin disease, lymphoma, multiple myeloma, chronic renal failure, nephrotic syndrome, immunosuppression, HIV infection, cigarette smokers ages 19 years and older), who previously have not received PCV13 or whose pneumococcal vaccination history is unknown	Choose either: PCV20 or PCV15 followed by PPSV23 1 year later (can consider an 8-week interval between PCV15 and PPSV23)	C: Severe allergic reaction to a vaccine component or after a prior dose P: Moderate or severe acute illness	Persons who have previously received PCV13 should receive PPSV23. If PPSV23 is unavailable, they may receive PCV20
Poliomyelitis	Inactivated poliovirus vaccine (IPV)	Certain adults who are at greater risk of exposure to wild-type or vaccine-derived poliovirus than the general population, including laboratory workers, health care workers, and travelers to countries where poliomyelitis is epidemic or endemic or specific populations with disease caused by poliovirus	For unvaccinated adults, two 0.5-mL doses IM or SQ 4 weeks apart and a third dose 6-12 months after the second; if <4 weeks available before protection is needed, a single dose of IPV and ensure that the series is complete after travel For incompletely immunized adults, complete primary series of three doses of IPV or prior oral poliovirus vaccine (OPV); no need to restart interrupted series; a mixed series can be considered complete A single dose of IPV can be given to adults who previously received a primary series but now are at high risk, such as those traveling to an endemic area	C: Severe allergic reaction to a vaccine component or after a prior dose P: On theoretical grounds, pregnant persons should not receive IPV, but if immediate protection is needed, IPV can be used P: Moderate or severe acute illness	
Rabies	Inactivated vaccine, HDCV or PCECV	High-risk persons, including animal handlers, selected laboratory and field workers, and persons traveling for ≥1 month to areas with high risk of rabies	Preexposure prophylaxis: for persons 18 years old and older, two doses of 1 mL IM on days 0 and 7 Confirmation of immunity recommended for laboratory workers, bat handlers, and animal handlers	C: History of severe hypersensitivity reaction P: Moderate or severe acute illness	Further doses needed after exposure Persons traveling to high-risk areas should receive booster dose at 1 to 3 years

TABLE 15-2 SELECTED IMMUNIZING AGENTS INDICATED FOR ADULTS*—cont'd

DISEASE	IMMUNIZING AGENT	INDICATIONS	SCHEDULE	MAJOR CONTRAINDICATIONS (C) AND PRECAUTIONS (P)	COMMENTS
Rubella	Live virus vaccine (with mumps and measles [MMR])	Adults, particularly persons of childbearing age, who lack history of rubella vaccine, laboratory confirmation of disease, and detectable rubella-specific antibodies in serum Persons in institutions where rubella outbreaks may occur, such as hospitals, the military, and colleges Persons born before 1957, except those who can become pregnant, generally can be considered immune	One 0.5-mL SQ dose	C: Pregnancy, altered immunity (e.g., leukemia, lymphoma, generalized malignant disease, congenital immunodeficiency, immunosuppressive therapy) C: Anaphylactic hypersensitivity to neomycin C: Administration of blood products should not contraindicate postpartum vaccination P: Thrombocytopenia if administered with measles vaccine P: Immune globulin or other blood products within prior 3 to 11 months P: Moderate or severe acute illness	People who can become pregnant should be counseled to avoid pregnancy for 1 month after vaccination
Smallpox (two types of vaccines)	Live vaccinia virus	Persons working with orthopox viruses	One 0.0025-mL dose intracutaneously with a bifurcated needle Boosters every 10 years and perhaps every 3 years for persons working with virulent orthopox viruses	C: History or presence of eczema or other acute, chronic, or exfoliative skin condition in patient or a close household or personal contact C: Immunosuppression or pregnancy in patient or a close household or personal contact C: Breast-feeding C: Allergy to a vaccine component P: History of heart disease P: Moderate or severe acute illness No contraindications if exposed to smallpox	Some complications of vaccination are treatable with vaccinia immune globulin Vaccine is effective 3-4 days after exposure to variola and perhaps longer to prevent or to modify the illness Serious adverse events are rare but significant, including eczema vaccinatum, progressive vaccinia, myopericarditis, autoinoculation, and encephalitis Vaccinia is transmissible
	Live, nonreplicating vaccinia vector vaccine	Adults at risk for smallpox or monkeypox infection	Two 0.5-mL doses SQ, 4 weeks apart	P: Allergy to a vaccine component (based on FDA package insert) P: Altered immunocompetence	
Tetanus	Tetanus and diphtheria toxoids combined (Td) Adult preparation of pertussis antigens combined with tetanus and diphtheria toxoids (Tdap)	All adults	For incompletely immunized adults, three total 0.5-mL doses IM needed for primary series: two doses IM 4 weeks apart, third dose 6-12 month after second dose; preferable that first dose is Tdap, subsequent doses can be Tdap or Td Booster (Tdap or Td) every 10 years No need to repeat if schedule is interrupted	C: History of neurologic or severe allergic reaction after a prior dose C: History of neurologic reaction after a previous dose (Tdap only) P: Moderate or severe acute illness P: Guillain-Barré syndrome <6 weeks after previous dose of tetanus-toxoid–containing vaccine	Special recommendations for wound treatment (see text) Persons with Guillain-Barré syndrome within the first 6 weeks after immunization, particularly adults who received a prior primary series, probably should not be revaccinated in most circumstances One-time booster of Tdap for all adults
Typhoid fever	Vi capsular polysaccharide vaccine Live attenuated Ty21a oral vaccine	Travelers to areas where the risk of prolonged exposure to contaminated food and water is high May be considered for family and intimate contacts of carriers and laboratory workers who work with *Salmonella* Typhi	Vi polysaccharide vaccine: one dose IM 0.5 mL; boosters every 2 years Oral vaccine: four doses on alternate days; repeat series every 5 years if risk continues	C: Severe local or systemic reaction to a prior dose C: Ty21a vaccine should not be administered to persons with altered immunity or those receiving antimicrobial agents P: Moderate or severe acute illness	Cumulative efficacy at 2.5 to 3.0 years: Vi capsular polysaccharide: 55%, Ty21a: 48% Food and water precautions essential

TABLE 15-2 SELECTED IMMUNIZING AGENTS INDICATED FOR ADULTS*—cont'd

DISEASE	IMMUNIZING AGENT	INDICATIONS	SCHEDULE	MAJOR CONTRAINDICATIONS (C) AND PRECAUTIONS (P)	COMMENTS
Varicella (primary infection; see herpes zoster for secondary prevention)	Live attenuated Oka strain of varicella-zoster virus (VAR)	All persons without evidence of varicella immunity	Two 0.5 mL doses SQ 4-8 weeks apart for adults A second dose is recommended for all persons who previously received one dose	C: Immunocompromise C: Pregnancy C: Allergy to vaccine components P: Immune globulin or other blood products within prior 3 to 11 months P: Moderate or severe acute illness	Adults born in the United States before 1980 (except health care workers, pregnant persons, and immunocompromised persons), or persons with clinician-diagnosed or verified history of varicella or herpes zoster can be considered immune Vaccine virus has rarely been transmitted to contacts from healthy vaccinees in whom rash developed Persons who receive vaccine should not become pregnant for 1 month
Yellow fever	Live attenuated virus (17D strain)	Persons living or traveling in areas where yellow fever exists	One 0.5 mL dose SQ booster every 10 years for at-risk laboratory personnel and certain travelers (pregnant persons, hematopoietic stem cell transplant recipients vaccinated before transplant, HIV-infected persons, and travelers who will be in a higher-risk setting based on season, location, activities, and duration of their travel, such as travelers who plan to spend a prolonged period in endemic areas or those traveling to highly endemic areas such as rural West Africa during peak transmission season or an area with an ongoing outbreak)	C: Immunocompromised persons C: History of anaphylactic allergies to eggs P: Pregnancy on theoretical grounds, although may be given if risk is high P: Moderate or severe acute illness	Fever, jaundice, and multiple-organ system failure (viscerotropic disease) have been rarely reported in first-time recipients of 17D-derived yellow fever vaccinations Vaccinate only persons traveling to areas where yellow fever is endemic.

*See the text and package inserts for further details, particularly regarding indications, dosage, administration, side effects, and adverse reactions and contraindications.

ACIP = Advisory Committee on Immunization Practices; COVID = coronavirus disease; FDA = U.S. Food and Drug Administration; HBsAg = hepatitis B surface antigen; HBV = hepatitis B virus; HDCV = human diploid cell vaccine for rabies; HIV = human immunodeficiency virus; HPV = human papillomavirus; IM = intramuscularly; IPV = inactivated poliovirus vaccine; MMR = measles, mumps, and rubella vaccine; OPV = live trivalent, bivalent, or monovalent oral poliovirus vaccine; PCECV = purified chick embryo cell culture rabies vaccine; SARS = severe acute respiratory syndrome; SQ = subcutaneously.

specific antigens (such as tetanus immune globulin). Most immune globulins must be injected intramuscularly, although intravenous and subcutaneous preparations are also available. Antitoxins are solutions of antibodies derived from animals immunized with specific antigens (e.g., diphtheria antitoxin). Passive immunization usually is indicated to protect individuals immediately before anticipated exposure or shortly after known or suspected exposure to an infectious agent (see Table 15-1), when active immunization either is not possible or has not been adequate.

ROUTE AND TIMING OF VACCINATION

Each immunobiologic has a preferred site and route of administration. In adults, vaccines intended for intramuscular injection should preferably be administered in the deltoid muscle. For most adults, intramuscular injections should be administered with a 1- to 1½-inch, 22- to 25-gauge needle. Use of the buttocks is discouraged except when volumes larger than 4 mL per injection are required because of the potential for damage to the sciatic nerve and because of diminished immune response to some vaccines (such as hepatitis B), probably because vaccine is injected into fat rather than into muscle. Subcutaneous vaccines are usually administered in the triceps area. In general, inactivated vaccines and toxoids can be given at the same visit at different sites. Live and inactivated vaccines usually can be administered at the same time. For example, measles, mumps, and rubella (MMR) vaccine can be administered at the same time as inactivated poliovirus vaccine and live attenuated varicella vaccine. In general, injected and intranasally administered live vaccines not delivered on the same day should be separated by at least 4 weeks to avoid interference with viral replication of the second vaccine by the first vaccine; if viral replication is hampered, a reduced immune response will occur. Orally administered live vaccines (such as oral typhoid vaccine) can be administered at any interval before or after live injected or intranasal vaccines. Immune globulin may interfere with the replication of injected live vaccine viruses; ideally, most live vaccines should be administered at least 2 weeks before or 3 to 11 months after receipt of immune globulin. Immune globulin does not interfere with the response to yellow fever vaccine and is not believed to interfere with orally or intranasally administered live virus vaccines.

CONTRAINDICATIONS AND PRECAUTIONS

Persons who administer vaccines should screen patients for contraindications and precautions to the vaccine before each dose of vaccine is administered (see Table 15-2). Screening is facilitated by consistent use of screening questionnaires, which are available from some state vaccination programs and other sources (e.g., Immunize.org, https://www.immunize.org). A contraindication is a condition that increases the risk for a serious adverse reaction. A vaccine should not be administered when a contraindication is present; for example, MMR vaccine should not be administered to severely immunocompromised persons. The only contraindication applicable to all vaccines is a history of a severe allergic reaction (e.g., anaphylaxis) after a previous dose of that vaccine or a vaccine component (unless the recipient has been desensitized). In addition, severely immunocompromised persons generally should not receive live vaccines. Because of the theoretical risk to the fetus, persons known to be pregnant generally should not receive live, attenuated vaccines.

A precaution is a condition that may increase the risk for a serious adverse reaction (i.e., a person may experience a more severe reaction to the vaccine than would have otherwise been expected, but the risk is less than the risk expected with a contraindication); may compromise the ability of the vaccine to produce immunity (e.g., administering measles vaccine to a person with passive immunity to measles from a blood transfusion); or may interfere with the diagnosis of another condition. In most cases, vaccinations should be deferred when a precaution is present. However, a vaccination may be indicated despite a precaution if the benefit of protection from the vaccine outweighs the risk for an adverse reaction. For example, a dose of combined tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis (Tdap) should be considered for a person in a community with a pertussis outbreak even if that person previously developed Guillain-Barré syndrome (Chapter 388) after a dose of pertussis-containing vaccine. The presence of a moderate or severe acute illness with or without a fever is a precaution to administration of all vaccines.

The egg protein contained in vaccines grown in chicken eggs (influenza [except cell-culture and recombinant] and yellow fever vaccines) may cause reactions in persons severely allergic to eggs. Persons who have experienced only hives following egg exposure should receive influenza vaccines as recommended. Persons whose reactions to eggs include symptoms other than hives, such as angioedema, respiratory distress, lightheadedness, or recurrent emesis, or who required epinephrine or another emergency medical intervention may similarly receive any licensed influenza vaccine that is otherwise appropriate for their age and health status, but such individuals should be vaccinated in an inpatient or outpatient medical setting, supervised by a health care provider who is able to recognize and manage severe allergic reactions.

If a person has a severe egg sensitivity or has a positive skin test to yellow fever vaccine but the vaccination is recommended because of the travel destination–specific risk, desensitization can be performed under direct supervision of a physician experienced in the management of anaphylaxis. For such persons receiving influenza and/or yellow fever vaccines, the vaccines should be administered in an inpatient or outpatient medical setting (including, but not necessarily limited to, hospitals, clinics, health departments, and physicians' offices) and be supervised by a health care provider who is able to recognize and manage severe allergic conditions. Although measles and mumps vaccines are grown in chick embryo tissue culture, the risk of anaphylaxis even in persons with severe hypersensitivity to eggs is low, so they can be vaccinated without prior skin testing.

Vaccine providers should consider observing patients for 15 minutes following administration of any vaccine to decrease the risk for injury should syncope occur.

ADVERSE REACTIONS

All vaccines are associated with some adverse reactions. Adverse reactions fall into three general categories: local, systemic, and allergic, including anaphylactic. Local reactions, such as pain or redness at the injection site, are generally the most frequent but least severe. Systemic adverse reactions include fever, malaise, myalgias (muscle pain), headache, and loss of appetite. These symptoms, which are common and nonspecific, may occur in vaccinated persons because of the vaccine or because of something unrelated to the vaccine. Antipyretics should not be administered routinely before or at the time of vaccination because they appear to reduce the immune response,[A1,A2] but they can be used for the treatment of fever and local discomfort that may occur after vaccination. Anaphylactic allergic reactions, which are the least frequent but most severe of such reactions, may be caused by the vaccine antigen itself; by another component of the vaccine, such as the cell culture material, stabilizer (e.g., gelatin), preservative, or antibiotic used to inhibit bacterial growth; or by vaccine packaging content (i.e., latex). Life-threatening anaphylactic reactions occur at a rate of about one per million doses.

Suspected adverse events temporally related to vaccinations should be reported to the Vaccine Adverse Event Reporting System (at www.vaers.hhs.gov). The National Vaccine Injury Compensation Program was established in the 1980s to compensate individuals who experience certain health events after vaccination on a "no-fault" basis. No-fault means that persons filing claims are not required to prove negligence on the part of either the health care provider or manufacturer to receive compensation. The program covers all routinely recommended childhood vaccinations, although adults who receive a covered vaccine may also file a claim. Claims may be based on the Vaccine Injury (see https://www.hrsa.gov/sites/default/files/hrsa/vaccine-compensation/vaccine-injury-table.pdf), which lists the adverse events associated with vaccines and is updated periodically.

GENERAL CONSIDERATIONS

The major group in the United States that makes comprehensive, detailed, evidence-based recommendations regarding immunization of adults is the Advisory Committee on Immunization Practices (ACIP) of the Centers for Disease Control and Prevention, which publishes its recommendations in the *Morbidity and Mortality Weekly Report* (also available at http://www.cdc.gov/vaccines/schedules/hcp/adult.html). Immunizations for adults depend on age, lifestyle, occupation, and medical conditions. Two adult immunization schedules are available, one based on age group (Fig. 15-1 and E-Table 15-1 and 15-2) and one based on underlying risk (Fig. 15-2 and see Table 15-2). Other vaccines recommended for travel and bioterrorism exposures are not included in these two figures but are discussed later.

All adults who have not received a primary series of diphtheria-tetanus-pertussis–containing vaccine as children should receive a series of three tetanus and diphtheria toxoid–containing vaccines, with the preferred schedule of 1 dose of Tdap, followed by 1 dose of either Td or Tdap at least 4 weeks afterward, and 1 dose of either Td or Tdap 6–12 months later.[2–4] All adults who received a diphtheria-tetanus-pertussis (DTaP) vaccine series as children should receive a dose of Tdap followed by decennial doses of Tdap or Td. In circumstances where a tetanus-toxoid–containing or diphtheria-toxoid–containing vaccine is recommended, such as for wound care, either Tdap or Td may be administered.

In circumstances where Td is recommended, either Tdap or Td can be administered. Persons born in or after 1957 should have evidence of immunity to measles, mumps, and rubella (e.g., documentation of vaccination or presence of antibodies considered compatible with protection). Adults without evidence of immunity to varicella (documentation of age-appropriate vaccination with two doses of a varicella-containing vaccine [varicella vaccine or MMRV]; laboratory evidence of immunity or confirmation of disease; birth in the United States before 1980, except for health care personnel or pregnant persons; or diagnosis or verification of a history of varicella or herpes zoster disease by a health care provider) should receive the varicella vaccine. Adults 50 years and older should receive two doses of the recombinant zoster subunit vaccine.

All persons younger than age 27 years should receive a human papillomavirus (HPV) vaccine series. Catch-up vaccination is not recommended for all adults; instead, shared clinical decision making, which requires a conversation between a provider and a potential vaccine recipient, is recommended for persons 27 through 45 years.

All persons ages 65 years or older and adults ages 19 years through 64 years who are at high risk for invasive pneumococcal disease (see Table 15-2), who have not received PCV13, or whose pneumococcal vaccination history is unknown should receive either a dose of PCV20 or a dose of PCV15 followed by PPSV23 1 year later (providers may consider an interval of 8 weeks between PCV15 and PPSV23).

Influenza vaccination is recommended annually for all persons 6 months of age or older, including all health care personnel. Health care workers exposed to blood or blood products should receive hepatitis B vaccine. Health care workers should also be immune to measles, mumps, rubella, tetanus, diphtheria, pertussis, and varicella.

ALTERED IMMUNOCOMPETENCE

Patients with altered immunocompetence (also referred to as immunocompromise, immunodeficiency, and immunosuppression) include persons with immunodeficiency diseases, leukemia, lymphoma, and generalized malignant disease and those who are immunosuppressed from therapy with corticosteroids, alkylating agents, antimetabolites, and radiation generally should not receive live vaccines (E-Table 15-3). Qualifications exist with one type of altered immunocompetence, infection with HIV. Two doses of MMR vaccine are recommended for all persons aged 12 months and older who have HIV infection and do not have evidence of immunity to measles, rubella, and mumps and who are not severely immunosuppressed (i.e., a CD4 percentage ≥15% and $CD4^+$ lymphocyte counts ≥200 cells/μL for ≥6 months for persons aged >5 years). Varicella vaccination (two doses, 3 months apart) may be considered in HIV-infected persons with $CD4^+$ T-lymphocyte counts above 200 cells/μL. Patients with leukemia in remission who have not been receiving any chemotherapy for at least 3 months may receive live virus vaccines. Short-course therapy (<2 weeks) with corticosteroids, alternate-day regimens with low to moderate doses of short-acting corticosteroids, and topical applications or tendon injections are not ordinarily contraindications to the administration of live vaccines.

Immunocompromised patients can receive inactivated vaccines and toxoids, although the efficacy of such preparations may be diminished.[5] Patients with

E-TABLE 15-1 FOOTNOTES: RECOMMENDED IMMUNIZATION SCHEDULE FOR ADULTS AGED 19 YEARS OR OLDER, UNITED STATES, 2023

Notes

For vaccine recommendations for persons 18 years of age or younger, see the Recommended Child and Adolescent Immunization Schedule.

COVID-19 vaccination

Routine vaccination
- **Primary series:** 2-dose series at 0, 4-8 weeks (Moderna) or 2-dose series at 0, 3-8 weeks (Novavax, Pfizer-BioNTech)
- **Booster dose:** see www.cdc.gov/vaccines/covid-19/clinical-considerations/interim-considerations-us.html

Special situations

Persons who are moderately or severely immunocompromised
- **Primary series**
  - 3-dose series at 0, 4, 8 weeks (Moderna) or 3-dose series at 0, 3, 7 weeks (Pfizer-BioNTech)
  - 2-dose series at 0, 3 weeks (Novavax)
- **Booster dose:** see www.cdc.gov/vaccines/covid-19/clinical-considerations/interim-considerations-us.html
- **Pre-exposure prophylaxis (e.g., monoclonal antibodies)** may be considered to complement COVID-19 vaccination. See www.cdc.gov/vaccines/covid-19/clinical-considerations/interim-considerations-us.html#immunocompromised

For Janssen COVID-19 Vaccine recipients see COVID-19 schedule at www.cdc.gov/vaccines/covid-19/clinical-considerations/interim-considerations-us.html.

Note: Current COVID-19 schedule available at www.cdc.gov/vaccines/covid-19/downloads/COVID-19-immunization-schedule-ages-6months-older.pdf.

For more information on Emergency Use Authorization (EUA) indications for COVID-19 vaccines, please visit www.fda.gov/emergency-preparedness-and-response/coronavirus-disease-2019-covid-19/covid-19-vaccines

***Haemophilus influenzae* type b vaccination**

Special situations
- **Anatomical or functional asplenia (including sickle cell disease):** 1 dose if previously did not receive Hib; if elective splenectomy, 1 dose, preferably at least 14 days before splenectomy
- **Hematopoietic stem cell transplant (HSCT):** 3-dose series 4 weeks apart starting 6–12 months after successful transplant, regardless of Hib vaccination history

Hepatitis A vaccination

Routine vaccination
- **Not at risk but want protection from hepatitis A** (identification of risk factor not required): 2-dose series HepA (Havrix 6–12 months apart or Vaqta 6–18 months apart [minimum interval: 6 months]) or 3-dose series HepA-HepB (Twinrix at 0, 1, 6 months [minimum intervals: dose 1 to dose 2: 4 weeks / dose 2 to dose 3: 5 months])

Special situations
- **At risk for hepatitis A virus infection:** 2-dose series HepA or 3-dose series HepA-HepB as above
  - **Chronic liver disease** (e.g., persons with hepatitis B, hepatitis C, cirrhosis, fatty liver disease, alcoholic liver disease, autoimmune hepatitis, alanine aminotransferase [ALT] or aspartate aminotransferase [AST] level greater than twice the upper limit of normal)
  - **HIV infection**
  - **Men who have sex with men**
  - **Injection or noninjection drug use**
  - **Persons experiencing homelessness**
  - **Work with hepatitis A virus** in research laboratory or with nonhuman primates with hepatitis A virus infection
  - **Travel in countries with high or intermediate endemic hepatitis A** (HepA-HepB [Twinrix] may be administered on an accelerated schedule of 3 doses at 0, 7, and 21–30 days, followed by a booster dose at 12 months)
  - **Close, personal contact with international adoptee** (e.g., household or regular babysitting) in first 60 days after arrival from country with high or intermediate endemic hepatitis A (administer dose 1 as soon as adoption is planned, at least 2 weeks before adoptee's arrival)
  - **Pregnancy** if at risk for infection or severe outcome from infection during pregnancy
  - **Settings for exposure,** including health care settings targeting services to injection or noninjection drug users or group homes and nonresidential day care facilities for developmentally disabled persons (individual risk factor screening not required)

Hepatitis B vaccination

Routine vaccination
- **Age 19 through 59 years: complete a 2- or 3- or 4-dose series**
  - 2-dose series only applies when 2 doses of Heplisav-B* are used at least 4 weeks apart
  - 3-dose series Engerix-B, PreHevbrio*, or Recombivax HB at 0, 1, 6 months [minimum intervals: dose 1 to dose 2: 4 weeks / dose 2 to dose 3: 8 weeks / dose 1 to dose 3: 16 weeks])
  - 3-dose series HepA-HepB (Twinrix at 0, 1, 6 months [minimum intervals: dose 1 to dose 2: 4 weeks / dose 2 to dose 3: 5 months])
  - 4-dose series HepA-HepB (Twinrix) accelerated schedule of 3 doses at 0, 7, and 21–30 days, followed by a booster dose at 12 months

***Note:** Heplisav-B and PreHevbrio are not recommended in pregnancy due to lack of safety data in pregnant persons.

- **Age 60 years or older with** known risk factors for hepatitis B virus infection **should** complete a HepB vaccine series.
- **Age 60 years or older without** known risk factors for hepatitis B virus infection **may** complete a HepB vaccine series.
  - **Risk factors for hepatitis B virus infection include:**
    - **Chronic liver disease** (e.g., persons with hepatitis C, cirrhosis, fatty liver disease, alcoholic liver disease, autoimmune hepatitis, alanine aminotransferase [ALT] or aspartate aminotransferase [AST] level greater than twice upper limit of normal)
    - **HIV infection**
    - **Sexual exposure risk** (e.g., sex partners of hepatitis B surface antigen [HBsAg]-positive persons; sexually active persons not in mutually monogamous relationships; persons seeking evaluation or treatment for a sexually transmitted infection; men who have sex with men)
    - **Current or recent injection drug use**
    - **Percutaneous or mucosal risk for exposure to blood** (e.g., household contacts of HBsAg-positive persons; residents and staff of facilities for developmentally disabled persons; health care and public safety personnel with reasonably anticipated risk for exposure to blood or blood-contaminated body fluids; persons on maintenance dialysis, including in-center or home hemodialysis and peritoneal dialysis, and persons who are predialysis; patients with diabetes)
    - **Incarceration**
    - **Travel in countries with high or intermediate endemic hepatitis B**

Special situations
- **Patients on dialysis:** complete a 3- or 4-dose series
  - 3-dose series Recombivax HB at 0, 1, 6 months (note: use Dialysis Formulation 1 mL = 40 mcg)
  - 4-dose series Engerix-B at 0, 1, 2, and 6 months (note: use 2 mL dose instead of the normal adult dose of 1 mL)

E-TABLE 15-1 FOOTNOTES: RECOMMENDED IMMUNIZATION SCHEDULE FOR ADULTS AGED 19 YEARS OR OLDER, UNITED STATES, 2023—cont'd

Human papillomavirus vaccination

Routine vaccination

- **HPV vaccination recommended for all persons through age 26 years:** 2- or 3-dose series depending on age at initial vaccination or condition:
  - **Age 15 years or older at initial vaccination:** 3-dose series at 0, 1–2 months, 6 months (minimum intervals: dose 1 to dose 2: 4 weeks / dose 2 to dose 3: 12 weeks / dose 1 to dose 3: 5 months; repeat dose if administered too soon)
  - **Age 9–14 years at initial vaccination and received 1 dose or 2 doses less than 5 months apart:** 1 additional dose
  - **Age 9–14 years at initial vaccination and received 2 doses at least 5 months apart:** HPV vaccination series complete, no additional dose needed
- **Interrupted schedules:** If vaccination schedule is interrupted, the series does not need to be restarted
- **No additional dose recommended when any HPV vaccine series has been completed using the recommended dosing intervals.**

Shared clinical decision-making

- **Some adults age 27–45 years:** Based on shared clinical decision-making, 2- or 3-dose series as above

Special situations

- **Age ranges recommended above for routine and catch-up vaccination or shared clinical decision-making also apply in special situations**
  - **Immunocompromising conditions, including HIV infection:** 3-dose series, even for those who initiate vaccination at age 9 through 14 years.
  - **Pregnancy:** Pregnancy testing is not needed before vaccination; HPV vaccination is not recommended until after pregnancy; no intervention needed if inadvertently vaccinated while pregnant.

Influenza vaccination

Routine vaccination

- **Age 19 years or older:** 1 dose any influenza vaccine appropriate for age and health status annually
- **Age 65 years or older:** Any one of quadrivalent high-dose inactivated influenza vaccine (HD-IIV4), quadrivalent recombinant influenza vaccine (RIV4), or quadrivalent adjuvanted inactivated influenza vaccine (aIIV4) is preferred. If none of these three vaccines is available, then any other age-appropriate influenza vaccine should be used.
- For the 2022–2023 season, see www.cdc.gov/mmwr/volumes/71/rr/rr7101a1.htm
- For the 2023–2024 season, see the 2023–2024 ACIP influenza vaccine recommendations.

Special situations

- **Egg allergy, hives only:** any influenza vaccine appropriate for age and health status annually
- **Egg allergy–any symptom other than hives** (e.g., angioedema, respiratory distress or required epinephrine or another emergency medical intervention): Any influenza vaccine appropriate for age and health status may be administered. If using egg-based IIV4 or LAIV4, administer in medical setting under supervision of health care provider who can recognize and manage severe allergic reactions.
- **Close contacts (e.g., caregivers, healthcare workers) of severely immunosuppressed persons who require a protected environment:** these persons should not receive LAIV4. If LAIV4 is given, they should avoid contact with/caring for such immunosuppressed persons for 7 days after vaccination.
- **Severe allergic reaction (e.g., anaphylaxis) to a vaccine component or a previous dose of any influenza vaccine:** see Appendix listing contraindications and precautions
- **History of Guillain-Barré syndrome within 6 weeks after previous dose of influenza vaccine:** Generally, should not be vaccinated unless vaccination benefits outweigh risks for those at higher risk for severe complications from influenza

Measles, mumps, and rubella vaccination

Routine vaccination

- **No evidence of immunity to measles, mumps, or rubella:** 1 dose
  - **Evidence of immunity:** Born before 1957 (health care personnel, see below), documentation of receipt of MMR vaccine, laboratory evidence of immunity or disease (diagnosis of disease without laboratory confirmation is not evidence of immunity)

Special situations

- **Pregnancy with no evidence of immunity to rubella:** MMR contraindicated during pregnancy; after pregnancy (before discharge from health care facility), 1 dose
- **Nonpregnant persons of childbearing age with no evidence of immunity to rubella:** 1 dose
- **HIV infection with CD4 percentages ≥15% and CD4 count ≥200 cells/mm^3 for at least 6 months and no evidence of immunity to measles, mumps, or rubella:** 2-dose series at least 4 weeks apart; MMR contraindicated for HIV infection with CD4 percentage <15% or CD4 count <200 cells/mm^3
- **Severe immunocompromising conditions:** MMR contraindicated
- **Students in postsecondary educational institutions, international travelers, and household or close, personal contacts of immunocompromised persons with no evidence of immunity to measles, mumps, or rubella:** 2-dose series at least 4 weeks apart if previously did not receive any doses of MMR or 1 dose if previously received 1 dose MMR
- **In mumps outbreak settings,** for information about additional doses of MMR (including 3rd dose of MMR), see www.cdc.gov/mmwr/volumes/67/wr/mm6701a7.htm
- **Health care personnel:**
  - **Born before 1957 with no evidence of immunity to measles, mumps, or rubella:** Consider 2-dose series at least 4 weeks apart for protection against measles or mumps or 1 dose for protection against rubella
  - **Born in 1957 or later with no evidence of immunity to measles, mumps, or rubella:** 2-dose series at least 4 weeks apart for protection against measles or mumps or at least 1 dose for protection against rubella

Meningococcal vaccination

Special situations for MenACWY

- **Anatomical or functional asplenia (including sickle cell disease), HIV infection, persistent complement component deficiency, complement inhibitor (e.g., eculizumab, ravulizumab) use:** 2-dose series MenACWY-D (Menactra, Menveo, or MenQuadfi) at least 8 weeks apart and revaccinate every 5 years if risk remains
- **Travel in countries with hyperendemic or epidemic meningococcal disease, or microbiologists routinely exposed to *Neisseria meningitidis*:** 1 dose MenACWY (Menactra, Menveo, or MenQuadfi) and revaccinate every 5 years if risk remains
- **First-year college students who live in residential housing (if not previously vaccinated at age 16 years or older) or military recruits:** 1 dose MenACWY (Menactra, Menveo, or MenQuadfi)
- For MenACWY **booster dose recommendations** for groups listed under "Special situations" and in an outbreak setting (e.g., in community or organizational settings and among men who have sex with men) and additional meningococcal vaccination information, see www.cdc.gov/mmwr/volumes/69/rr/rr6909a1.htm

Shared clinical decision-making for MenB

- **Adolescents and young adults age 16–23 years (age 16–18 years preferred) not at increased risk for meningococcal disease:** Based on shared clinical decision-making, 2-dose series MenB-4C (Bexsero) at least 1 month apart or 2-dose series MenB-FHbp (Trumenba) at 0, 6 months (if dose 2 was administered less than 6 months after dose 1, administer dose 3 at least 4 months after dose 2); MenB-4C and MenB-FHbp are not interchangeable (use same product for all doses in series)

Special situations for MenB

- **Anatomical or functional asplenia (including sickle cell disease), persistent complement component deficiency, complement inhibitor (e.g., eculizumab, ravulizumab) use, or microbiologists routinely exposed to *Neisseria meningitidis*:** 2-dose primary series MenB-4C (Bexsero) at least 1 month apart or 3-dose primary series MenB-FHbp (Trumenba) at 0, 1–2, 6 months (if dose 2 was administered at least 6 months after dose 1, dose 3 not needed; if dose 3 is administered earlier than 4 months after dose 2, a fourth dose should be administered at least 4 months after dose 3); MenB-4C and MenB-FHbp are not interchangeable (use same product for all doses in series); 1 dose MenB booster 1 year after primary series and revaccinate every 2–3 years if risk remains
- **Pregnancy:** Delay MenB until after pregnancy unless at increased risk and vaccination benefits outweigh potential risks
- For MenB **booster dose recommendations** for groups listed under "Special situations" and in an outbreak setting (e.g., in community or organizational settings and among men who have sex with men) and additional meningococcal vaccination information, see www.cdc.gov/mmwr/volumes/69/rr/rr6909a1.htm

Note: MenB vaccines may be administered simultaneously with MenACWY vaccines if indicated, but at a different anatomic site, if feasible.

E-TABLE 15-1 FOOTNOTES: RECOMMENDED IMMUNIZATION SCHEDULE FOR ADULTS AGED 19 YEARS OR OLDER, UNITED STATES, 2023—cont'd

Pneumococcal vaccination

Routine vaccination

- **Age 65 years or older who have:**
  - **Not previously received a dose of PCV13, PCV15, or PCV20 or whose previous vaccination history is unknown:** 1 dose PCV15 OR 1 dose PCV20. If PCV15 is used, this should be followed by a dose of PPSV23 given at least 1 year after the PCV15 dose. A minimum interval of 8 weeks between PCV15 and PPSV23 can be considered for adults with an immunocompromising condition,* cochlear implant, or cerebrospinal fluid leak to minimize the risk of invasive pneumococcal disease caused by serotypes unique to PPSV23 in these vulnerable groups.
  - **Previously received only PCV7:** follow the recommendation above.
  - **Previously received only PCV13:** 1 dose PCV20 at least 1 year after the PCV13 dose OR complete the recommended PPSV23 series as described here: www.cdc.gov/vaccines/vpd/pneumo/downloads/pneumo-vaccine-timing.pdf
  - **Previously received only PPSV23:** 1 dose PCV15 OR 1 dose PCV20 at least 1 year after the PPSV23 dose. If PCV15 is used, it need not be followed by another dose of PPSV23.
  - **Previously received both PCV13 and PPSV23 but NO PPSV23 was received at age 65 years or older:** 1 dose PCV20 at least 5 years after their last pneumococcal vaccine dose OR complete the recommended PPSV23 series as described here: www.cdc.gov/vaccines/vpd/pneumo/downloads/pneumo-vaccine-timing.pdf
  - **Previously received both PCV13 and PPSV23, AND PPSV23 was received at age 65 years or older:** Based on shared clinical decision-making, 1 dose of PCV20 at least 5 years after the last pneumococcal vaccine dose.
  - For guidance on determining which pneumococcal vaccines a patient needs and when, please refer to the mobile app which can be downloaded here: www.cdc.gov/vaccines/vpd/pneumo/hcp/pneumoapp.html

Special situations

- **Age 19–64 years with certain underlying medical conditions or other risk factors** who have**
  - **Not previously received a PCV13, PCV15, or PCV20 or whose previous vaccination history is unknown:** 1 dose PCV15 OR 1 dose PCV20. If PCV15 is used, this should be followed by a dose of PPSV23 given at least 1 year after the PCV15 dose. A minimum interval of 8 weeks between PCV15 and PPSV23 can be considered for adults with an immunocompromising condition,* cochlear implant, or cerebrospinal fluid leak
  - **Previously received only PCV7:** follow the recommendation above
  - **Previously received only PCV13:** 1 dose PCV20 at least 1 year after the PCV13 dose OR complete the recommended PPSV23 series as described here: www.cdc.gov/vaccines/vpd/pneumo/downloads/pneumo-vaccine-timing.pdf
  - **Previously received only PPSV23:** 1 dose PCV15 OR 1 dose PCV20 at least 1 year after the PPSV23 dose. If PCV15 is used, it need not be followed by another dose of PPSV23
  - **Previously received both PCV13 and PPSV23 but have not completed the recommended series:** 1 dose PCV20 at least 5 years after their last pneumococcal vaccine dose OR complete the recommended PPSV23 series as described here: www.cdc.gov/vaccines/vpd/pneumo/downloads/pneumo-vaccine-timing.pdf
- For guidance on determining which pneumococcal vaccines a patient needs and when, please refer to the mobile app which can be downloaded here: www.cdc.gov/vaccines/vpd/pneumo/hcp/pneumoapp.html

*__Note:__ Immunocompromising conditions include chronic renal failure, nephrotic syndrome, immunodeficiency, iatrogenic immunosuppression, generalized malignancy, human immunodeficiency virus, Hodgkin disease, leukemia, lymphoma, multiple myeloma, solid organ transplants, congenital or acquired asplenia, sickle cell disease, or other hemoglobinopathies.

**__Note:__ Underlying medical conditions or other risk factors include alcoholism, chronic heart/liver/lung disease, chronic renal failure, cigarette smoking, cochlear implant, congenital or acquired asplenia, CSF leak, diabetes mellitus, generalized malignancy, HIV, Hodgkin disease, immunodeficiency, iatrogenic immunosuppression, leukemia, lymphoma, multiple myeloma, nephrotic syndrome, solid organ transplants, or sickle cell disease, or other hemoglobinopathies.

Polio vaccination

Routine vaccination

Routine poliovirus vaccination of adults residing in the United States is not necessary.

Special situations

- Adults at increased risk of exposure to poliovirus with:
  - No evidence of a complete polio vaccination series (i.e., at least 3 doses): administer remaining doses (1, 2, or 3 doses) to complete a 3-dose series
  - Evidence of completed polio vaccination series (i.e., at least 3 doses): may administer one lifetime IPV booster

For detailed information, see: www.cdc.gov/vaccines/vpd/polio/hcp/recommendations.html

Tetanus, diphtheria, and pertussis (Tdap) vaccination

Routine vaccination

- **Previously did not receive Tdap at or after age 11 years:** 1 dose Tdap, then Td or Tdap every 10 years

Special situations

- **Previously did not receive primary vaccination series for tetanus, diphtheria, or pertussis:** 1 dose Tdap followed by 1 dose Td or Tdap at least 4 weeks later, and a third dose of Td or Tdap 6–12 months later (Tdap can be substituted for any Td dose, but preferred as first dose), Td or Tdap every 10 years thereafter
- **Pregnancy:** 1 dose Tdap during each pregnancy, preferably in early part of gestational weeks 27–36
- **Wound management:** Persons with 3 or more doses of tetanus-toxoid-containing vaccine: For clean and minor wounds, administer Tdap or Td if more than 10 years since last dose of tetanus-toxoid-containing vaccine; for all other wounds, administer Tdap or Td if more than 5 years since last dose of tetanus-toxoid-containing vaccine. Tdap is preferred for persons who have not previously received Tdap or whose Tdap history is unknown. If a tetanus-toxoid-containing vaccine is indicated for a pregnant woman, use Tdap. For detailed information, see www.cdc.gov/mmwr/volumes/69/wr/mm6903a5.htm

Varicella vaccination

Routine vaccination

- **No evidence of immunity to varicella:** 2-dose series 4–8 weeks apart if previously did not receive varicella-containing vaccine (VAR or MMRV [measles-mumps-rubella-varicella vaccine] for children); if previously received 1 dose varicella-containing vaccine, 1 dose at least 4 weeks after first dose
  - **Evidence of immunity:** U.S.-born before 1980 (except for pregnant persons and health care personnel [see below]), documentation of 2 doses varicella-containing vaccine at least 4 weeks apart, diagnosis or verification of history of varicella or herpes zoster by a health care provider, laboratory evidence of immunity or disease

Special situations

- **Pregnancy with no evidence of immunity to varicella:** VAR contraindicated during pregnancy; after pregnancy (before discharge from health care facility), 1 dose if previously received 1 dose varicella-containing vaccine or dose 1 of 2-dose series (dose 2: 4–8 weeks later) if previously did not receive any varicella-containing vaccine, regardless of whether U.S.-born before 1980
- **Health care personnel with no evidence of immunity to varicella:** 1 dose if previously received 1 dose varicella-containing vaccine; 2-dose series 4–8 weeks apart if previously did not receive any varicella-containing vaccine, regardless of whether U.S.-born before 1980
- **HIV infection with CD4 percentages ≥15% and CD4 count ≥200 cells/mm^3 with no evidence of immunity:** Vaccination may be considered (2 doses 3 months apart); VAR contraindicated for HIV infection with CD4 percentage <15% or CD4 count <200 cells/mm^3
- **Severe immunocompromising conditions:** VAR contraindicated

E-TABLE 15-1 FOOTNOTES: RECOMMENDED IMMUNIZATION SCHEDULE FOR ADULTS AGED 19 YEARS OR OLDER, UNITED STATES, 2023—cont'd

Zoster vaccination

Routine vaccination

- **Age 50 years or older*:** 2-dose series recombinant zoster vaccine (RZV, Shingrix) 2–6 months apart (minimum interval: 4 weeks; repeat dose if administered too soon), regardless of previous herpes zoster or history of zoster vaccine live (ZVL, Zostavax) vaccination.

*__Note:__ Serologic evidence of prior varicella is not necessary for zoster vaccination. However, if serologic evidence of varicella susceptibility becomes available, providers should follow ACIP guidelines for varicella vaccination first. RZV is not indicated for the prevention of varicella, and there are limited data on the use of RZV in persons without a history of varicella or varicella vaccination.

Special situations

- **Pregnancy:** There is currently no ACIP recommendation for RZV use in pregnancy. Consider delaying RZV until after pregnancy.
- **Immunocompromising conditions (including persons with HIV regardless of CD4 count)**:** 2-dose series recombinant zoster vaccine (RZV, Shingrix) 2–6 months apart (minimum interval: 4 weeks; repeat dose if administered too soon). For detailed information, see www.cdc.gov/shingles/vaccination/immunocompromised-adults.html

**__Note:__ If there is no documented history of varicella, varicella vaccination, or herpes zoster, providers should refer to the clinical considerations for use of RZV in immunocompromised adults aged ≥19 years and the ACIP varicella vaccine recommendations for further guidance: www.cdc.gov/mmwr/volumes/71/wr/mm7103a2.htm

E-TABLE 15-2 VACCINES IN THE ADULT IMMUNIZATION SCHEDULE

VACCINES	ABBREVIATIONS	TRADE NAMES
Haemophilus influenzae type b vaccine	Hib	ActHIB Hiberix PedvaxHIB
Hepatitis A vaccine	HepA	Havrix Vaqta
Hepatitis A and hepatitis B vaccine	HepA-HepB	Twinrix
Hepatitis B vaccine	HepB	Engerix-B Recombivax HB Heplisav-B PreHevbrio
Human papillomavirus vaccine	HPV	Gardasil 9
Influenza vaccine (inactivated)	IIV	Many brands
Influenza vaccine (live, attenuated)	LAIV4	FluMist Quadrivalent
Influenza vaccine (recombinant)	RIV4	Flublok Quadrivalent
Measles, mumps, and rubella vaccine	MMR	M-M-R II Priorix
Meningococcal serogroups A, C, W, Y vaccine	MenACWY-D MenACWY-CRM MenACWY-TT	Menactra Menveo MenQuadfi
Meningococcal serogroup B vaccine	MenB-4C MenB-FHbp	Bexsero Trumenba
Pneumococcal 13-valent conjugate vaccine	PCV13	Prevnar 13
Pneumococcal 15-valent conjugate vaccine	PCV15	Vaxneuvance
Pneumococcal 20-valent vaccine	PCV20	Prevnar 20
Pneumococcal 23-valent polysaccharide vaccine	PPSV23	Pneumovax 23
Tetanus and diphtheria toxoids	Td	Tenivac Tdvax
Tetanus and diphtheria toxoids and acellular pertussis vaccine	Tdap	Adacel Boostrix
Varicella vaccine	VAR	Varivax
Zoster vaccine, recombinant	RZV	Shingrix

E-TABLE 15-3 SPECIAL POPULATIONS THAT NEED ADDITIONAL CONSIDERATIONS

- **Pregnant persons.** Pregnant persons should receive the tetanus, diphtheria, and acellular pertussis vaccine (Tdap) during every pregnancy and the influenza vaccine during or before pregnancy. Live vaccines (e.g., measles, mumps, and rubella vaccine [MMR]) are contraindicated.
- **Asplenia.** Adults with anatomic or functional asplenia have specific vaccination recommendations because of their increased risk for infection by encapsulated bacteria. Anatomic or functional asplenia includes congenital or acquired asplenia, splenic dysfunction, sickle cell disease and other hemoglobinopathies, and splenectomy.
- **Altered immunocompetence.** Adults with high-level immunosuppression should generally avoid live vaccines. Inactivated vaccines (e.g., pneumococcal vaccines) are generally acceptable. High-level immunosuppression includes human immunodeficiency virus (HIV) infection with a CD4 cell count <200 cells/μL, receipt of daily corticosteroid therapy with ≥20 mg of prednisone or equivalent for ≥14 days, primary immunodeficiency disorder (e.g., severe combined immunodeficiency or complement component deficiency), and receipt of cancer chemotherapy. Other immunocompromising conditions and immunosuppressive medications to consider when vaccinating adults can be found in *IDSA Clinical Practice Guideline for Vaccination of the Immunocompromised Host.*[*] Additional information on vaccinating immunocompromised adults is in *General Best Practice Guidelines for Immunization.*[†]

*Rubin LG, Levin MJ, Ljungman P, et al. 2013 IDSA clinical practice guideline for vaccination of the immunocompromised host. *Clin Infect Dis*. 2014;58:e44-e100.

†Advisory Committee on Immunization Practices. Centers for Disease Control and Prevention. Available at https://www.cdc.gov/vaccines/hcp/acip-recs/general-recs/index.html.
Adapted from https://www.cdc.gov/vaccines/schedules/downloads/adult/adult-combined-schedule.pdf.

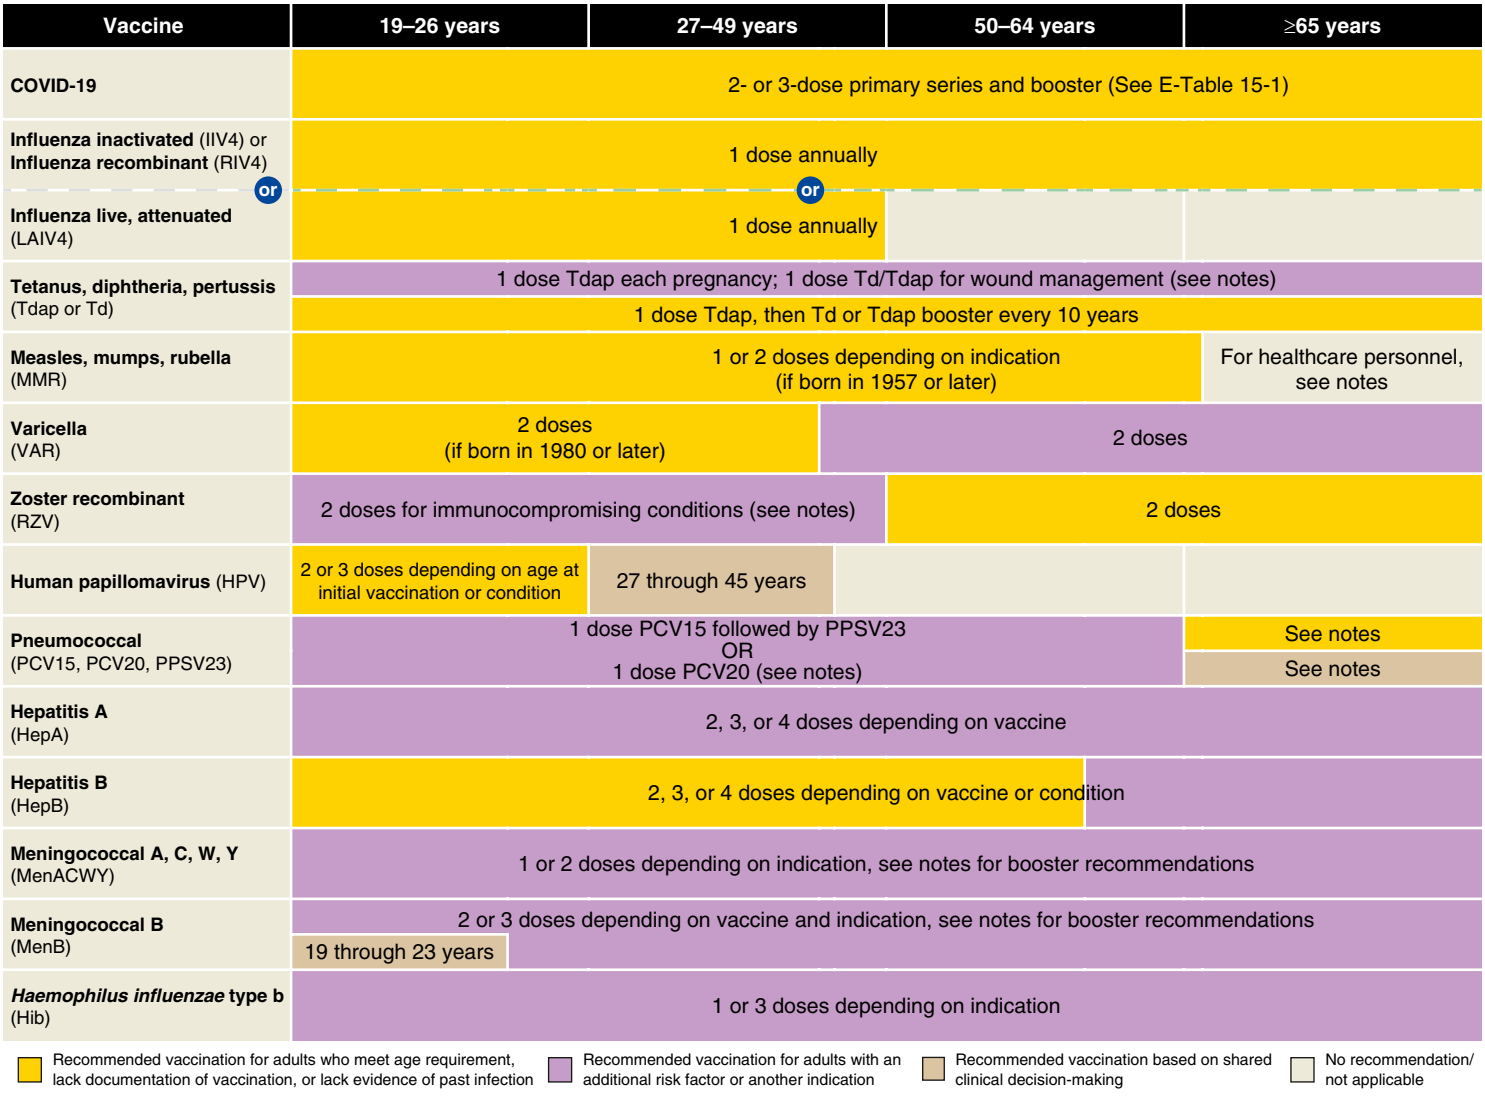

FIGURE 15-1. Recommended adult immunization schedule by age group, United States, 2023. See E-Table 15-1 for footnotes. COVID-19 = coronavirus disease 2019. (Adapted from https://www.cdc.gov/vaccines/schedules/downloads/adult/adult-combined-schedule.pdf.)

known HIV infection should receive PCV15 with PPSV23 1 year later (or PCV20 with no PPSV23); meningococcal serogroup ACWY vaccine; hepatitis A vaccine; hepatitis B vaccine; three doses of HPV vaccine (if not already vaccinated); and annual influenza vaccination.

PREGNANCY

In general, live vaccines should not be given to pregnant persons because of the theoretical concern that the vaccines could adversely affect the fetus (see E-Table 15-3). No significant adverse events have been documented as attributable to vaccination of pregnant persons with rubella-containing or varicella vaccines; nevertheless, pregnant persons should not receive MMR or varicella vaccine, and persons who do receive these vaccines should wait 1 month before becoming pregnant. Poliomyelitis and yellow fever vaccines usually should not be given to pregnant persons unless the risk of disease is substantial. Tdap vaccination is indicated for pregnant persons during each pregnancy, preferably early in the period between 27 and 36 weeks of gestation, to prevent pertussis in their infants and themselves. All pregnant persons should be screened for hepatitis B surface antigen (HBsAg). If HBsAg is positive, their infants should receive hepatitis B vaccine and hepatitis B immune globulin within 12 hours of birth. For persons who are pregnant, HPV vaccination should be delayed until after pregnancy; however, pregnancy testing is not needed before vaccination. Persons who are breast-feeding or lactating can receive the HPV vaccine. All persons who are or will be pregnant during the influenza season should receive inactivated influenza vaccine before or during pregnancy to protect themselves and their babies.

INDIVIDUAL IMMUNOBIOLOGICS

Immunobiologics for adults lacking evidence of prior infection, immunity, or documented vaccination, either for all adults at a certain age or because of one or more risk factors (health condition, lifestyle, occupation, or other indication), are discussed in the following sections.

COVID-19

In the United States as of April 2022, four intramuscular vaccines are available for prevention of coronavirus disease 2019 (COVID-19), infection with severe acute respiratory syndrome coronavirus 2 [SARS-CoV-2; Chapter 337]). Two of the vaccines (Pfizer BioNTech COVID-19 vaccine; Moderna COVID-19 vaccine) are messenger RNA (mRNA) vaccines consisting of SARS-CoV-2 mRNA. Following injection, the mRNA is translated by the host to generate SARS-CoV-2 spike protein, which acts as the antigen. A third vaccine (Johnson & Johnson's Janssen COVID-19 vaccine) is a non-replicating vector vaccine consisting of a non-replicating adenovirus vector with genes encoding for the coronavirus spike protein, which again is the antigen generating the immune response. A fourth vaccine (Novavax) consists of a recombinant spike protein nanoparticle.[6] After two doses 2 or more weeks apart, Pfizer-BioNTech COVID-19 vaccine and Moderna COVID-19 have 90 to 95% efficacy in preventing clinical disease in persons ages 16 years and older (Pfizer-BioNTech COVID-19 vaccine) and ages 18 years and older (Moderna COVID-19).[A3–A6] One dose of the Janssen vaccine has 66% efficacy in preventing laboratory-confirmed COVID-19 illness in persons 18 years old and older. All three vaccines have high efficacy against severe disease and death from COVID-19. A person is

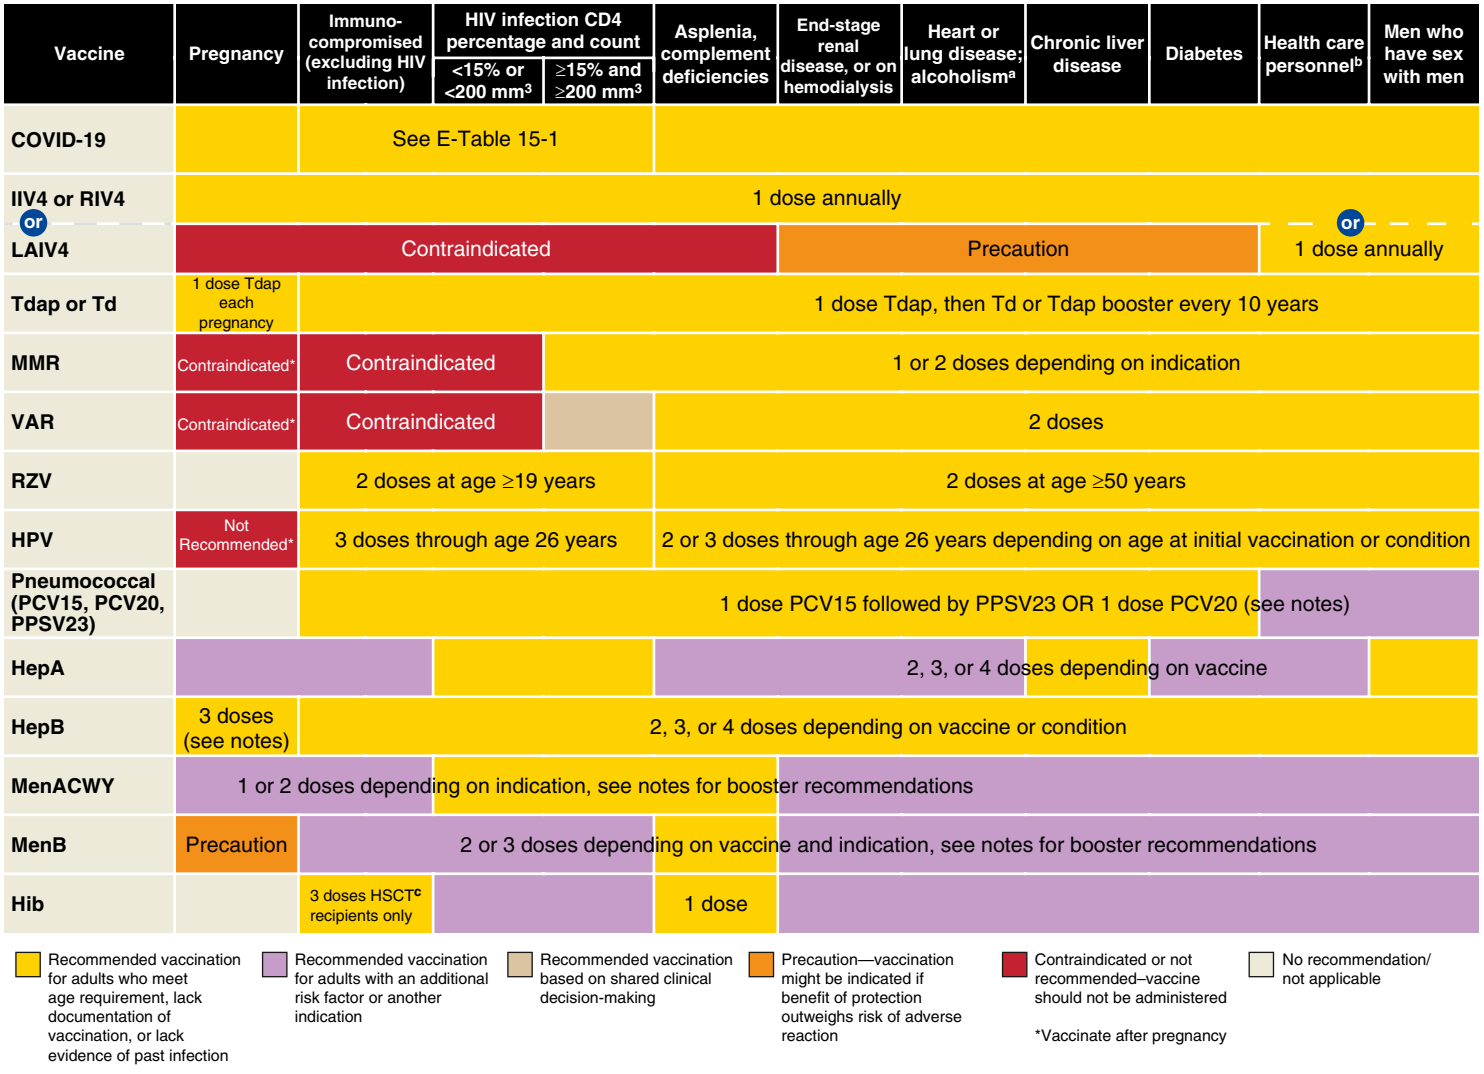

FIGURE 15-2. Recommended adult immunization schedule by medical condition or other indication, United States, 2023. [a]Precaution for LAIV4 does not apply to alcoholism. [b]See notes for influenza; hepatitis B; measles, mumps, and rubella; and varicella vaccinations. [c]Hematopoietic stem cell transplant. See E-Table 15-1 for footnotes. COVID-19 = coronavirus disease 2019. (Adapted from http://www.cdc.gov/vaccines/schedules/downloads/adult/adult-combined-schedule.pdf.)

considered fully vaccinated at 2 weeks or more after receipt of the recommended dose series.

Indications

COVID-19 vaccines are FDA-approved for a primary series in persons ages 12 years and older (Pfizer-BioNTech vaccine) and age 18 years and older (Moderna vaccine). COVID-19 vaccines are also FDA-authorized for emergency use as a primary series in persons ages 5 through 15 years (Pfizer-BioNTech COVID-19 vaccine), 12 years and older (Novavax COVID-19 vaccine), or ages 18 years or older (Janssen COVID-19 vaccine), as additional doses for immunosuppressed persons age 12 years and older (Pfizer-BioNTech and Moderna) and as booster doses (the mRNA vaccines COVID-19 vaccines).[7] Although mRNA vaccines are preferred as booster doses, Novavax may be used as a booster dose, but only if mRNA vaccines are unavailable or not desired. Novavax may only be used as a first booster dose.

COVID-19 vaccine is recommended for the prevention of SARS-CoV-2 infection. mRNA vaccines are preferred over Janssen COVID-19 vaccine.

The vaccines can be administered simultaneously with or at any interval from other vaccines. A third dose of an mRNA vaccine is recommended 28 days after the primary series for persons ages 5 years and older who are immunosuppressed.

A booster dose should be administered at least 2 months after the additional dose.[A7] A booster dose of mRNA vaccine is recommended at least 2 months after the primary series for persons ages 12 years or older. A booster dose is also recommended for persons 12 years old and older who were immunosuppressed upon receipt of the primary series and who received an additional dose. The current effectiveness of the booster against the most common circulating strain is 37 to 52% depending on the age of the adult.[8]

Adverse Reactions

After vaccination, about 35 to 90% of vaccine recipients experience local reactions and about 45 to 85% experience systemic reactions. Most of these reactions are mild and self-limited. Rare serious adverse events (Chapter 337) include anaphylactic reactions (presumably to vaccine components polyethylene glycol and polysorbate) and lymphadenopathy, Bell palsy (all vaccines), swelling at the site of previously implanted dermal fillers (Moderna COVID-19 vaccine), a syndrome of thrombosis with thrombocytopenia (Janssen COVID-19 vaccine), myopericarditis and pericarditis (mRNA COVID-19 vaccines), and Guillain-Barré syndrome (Janssen COVID-19 vaccine).[9] With the exception of the risk of anaphylaxis, which is low and exists with every vaccine, the low rate of these serious adverse reactions to date has not resulted in changes to the recommended use of these vaccines.

HAEMOPHILUS INFLUENZAE TYPE B VACCINE

*Haemophilus influenza*e type b (Hib) vaccines are composed of a polysaccharide capsule conjugated to a protein. There are two single-component vaccines (ActHib and PedvaxHib). ActHib is Hib polysaccharide from type b conjugated to a tetanus protein. PedvaxHib is Hib polysaccharide conjugated to an outer membrane protein of a strain of *Neisseria meningitidis*. There are two combination vaccines, ActHib combined with DTaP and IPV (Pentacel) and PedvaxHib combined with DTaP, IPV, and HepB (Vaxelis).

Indications

H. influenzae type b vaccine is recommended for adults who have anatomic and functional asplenia (e.g., sickle cell disease) who are vaccine naïve and adults who have received a haematopoietic cell transplant (HCT; Chapter 163). For naïve adults with functional and anatomic asplenia, one dose of Hib is recommended. For all adults post-HCT, regardless of previous vaccination, three doses of Hib are recommended with intervals of 1 month.

Adverse Reactions

The contraindication to Hib vaccine is a severe allergic reaction (e.g., anaphylaxis) following a prior dose or to a vaccine component. The precaution to Hib vaccine is severe or moderate acute illness.

HEPATITIS A

Two inactivated hepatitis A (Chapter 134) vaccines are available in the United States. Seroconversion rates after a single dose of either vaccine in persons older than 1 year exceed 95%, and protection is expected to persist for at least 25 years.

Indications

For adults, the vaccine is indicated primarily for persons traveling to countries (generally those in the developing world) with high or intermediate endemicity for hepatitis A, but it is also recommended for other groups at high risk for infection or for development of severe hepatitis. In addition, vaccine is routinely recommended for children 12 to 23 months of age, with catch-up through 18 years of age. Vaccination also is recommended for unvaccinated persons 1 year of age and older for postexposure prophylaxis after close contact with an infected person or exposure to a contaminated food or water source. For postexposure prophylaxis, persons 40 years of age and older who have altered immunocompetence or chronic liver disease should receive immune globulin in addition to hepatitis A vaccine. Health care workers have not been shown to be at higher risk than the general population for hepatitis A and do not need routine immunization. Although food handlers are not at increased risk for hepatitis A compared with the general population, the consequences of infection or suspected infection in this group, which can lead to extensive public health investigations, may make vaccination cost-effective in some settings. Doses vary by age and product. All schedules call for a second dose at least 6 months after the first dose.

Adverse Reactions

The most common adverse reaction after hepatitis A vaccination is tenderness and soreness at the injection site. Although rare and more serious adverse events have been reported in temporal association with vaccination, no causal relationships have been established.

HEPATITIS B

Hepatitis B (Chapter 134) vaccine was the first vaccine known to prevent cancer. It also can prevent acute and chronic complications of hepatitis B, including an estimated 1800 deaths annually in the United States from liver cancer, cirrhosis, and fulminant hepatic disease. Currently produced vaccines contain HBsAg derived from insertion of the gene for HBsAg into *Saccharomyces cerevisiae*. When it is administered in a three-dose series, hepatitis B vaccine produces adequate antibody responses (anti-HBs ≥10 mIU/mL) in more than 90% of healthy adults younger than 40 years and in more than 95% of healthy infants, children, and adolescents. By age 60 years, protective levels of antibody develop in only 75% of vaccinated persons. A new adjuvanted hepatitis B vaccine was licensed in 2017. It consists of recombinant HBsAg, produced in yeast cells *(Hansenula polymorpha)* combined with a novel cytosine phosphoguanine (CpG)–enriched oligodeoxynucleotide (ODN) phosphorothioate immunostimulatory adjuvant (CpG 1018 adjuvant). It is administered in a two-dose series, 1 month apart. The duration of vaccine-conferred immunity is not known, although follow-up of vaccinees for more than 20 years indicates persistence of protection against clinically significant infections (i.e., detectable viremia and clinical disease). Booster doses are not currently recommended. Vaccine must be injected intramuscularly in the deltoid.

Indications

Hepatitis B vaccine is indicated for all adults ages 18 through 59 years and for adults ages 60 years of age and older who are at increased risk of infection or increased risk of complications from hepatitis B infection (see Fig. 15-1 and E-Table 15-1), including all persons ages 19 through 59 years with diabetes. Vaccination of persons who are below age 60 years and without risk factors is based on shared clinical decision making. Universal screening for HBsAg is recommended for all pregnant persons; three doses of vaccine and one dose of hepatitis B immune globulin are recommended for infants of acutely or chronically infected mothers.

Postvaccination serologic testing is recommended for health care workers, immunosuppressed persons, and sexual contacts of persons with chronic hepatitis B infection. If the test is negative, one additional dose of vaccine should be given and the individual should be retested. If this second test is negative, the remaining doses of the series should be given. If the individual still has a negative serology, they are considered a nonresponder. Postvaccination serologic testing is recommended for patients on dialysis 1 year after the final dose in the series. If the test is negative, one booster dose should be given, with follow-up testing 1 year later and then annually.

Adverse Reactions

The most common adverse reaction is soreness at the injection site. Rare instances of Guillain-Barré syndrome, leukoencephalitis, optic neuritis, transverse myelitis, rheumatoid arthritis, type 1 diabetes, and autoimmune disease have been reported, but causal associations have not been confirmed with any systemic immune complications.

HUMAN PAPILLOMAVIRUS

Three licensed HPV vaccines (Chapter 344) contain virus-like particles of the L1 capsid protein of HPV types 16 and 18, which account for about 66% of cases of cervical cancer in the United States. HPV vaccines are prophylactic (i.e., they prevent new infections). These vaccines have reduced the incidence of vaccine-type HPV infection,[A8] as well as the risk of cervical intraepithelial neoplasia.[10] Two of these vaccines, bivalent and quadrivalent, remain licensed but are no longer available in the United States. The nine-valent vaccine (9vHPV) also contains virus-like particles of the L1 capsid protein of HPV types 6 and 11, which are the most common causes of anogenital warts. This vaccine also contains L1 capsid proteins of types 31, 33, 45, 52, and 58, which cause an additional 15% of cervical cancers. HPV type 16 accounts for most of the other cancers caused by HPV infection. Overall, 9vHPV can prevent over 90% of cancers that are caused by HPV.

Indications

Routine vaccination of 11- to 12-year-old girls and boys is recommended in a two-dose schedule at 0 and 6 to 12 months for persons initiating vaccination before age 15 years and a three-dose schedule at 0, 1 to 2, and 6 months for persons initiating vaccination at age 15 years or older or who are immunosuppressed. Vaccine can be given to persons starting at age 9 years. Catch-up vaccination is recommended for all persons through 26 years. Shared clinical decision making is recommended for adults who are age 27 through 45 years and who are not adequately vaccinated.

Adverse Reactions

The most commonly reported local symptoms are injection site pain, redness, and swelling. The most common generalized symptoms are dizziness, syncope, nausea, vomiting, fatigue, headache, fever, and urticaria.

INFLUENZA

Influenza vaccines for seasonal influenza include intramuscular inactivated influenza vaccine, recombinant influenza vaccine, containing the same four virus types as the inactivated vaccine, and intranasal live attenuated influenza vaccine. Live attenuated vaccine (LAIV), which consists of four cold-adapted, temperature-sensitive attenuated viruses, one for each of the expected circulating strains, uses viruses that have been reassorted with circulating strains to contain six internal genes from the parent virus and genes for the surface hemagglutinin and neuraminidase of an A(H3N2), A(H1N1), and two B strains.

Indications

Annual influenza (Chapter 332) vaccination is indicated for all adults, but especially persons at high risk of complications from the disease: all persons aged 50 years and older; adults who have chronic pulmonary, cardiovascular, renal, hepatic, neurologic, hematologic, or metabolic disorders; persons who are immunosuppressed; women who are or will be pregnant during the influenza season; residents of long-term care facilities; American Indians or Alaska Natives; and persons who are morbidly obese. To reduce transmission of influenza to high-risk patients, health care personnel and household contacts of high-risk patients, including contacts of children younger than 5 years, also should be vaccinated annually. Providers should offer vaccination

by the end of October, if possible. Pregnant persons in the third trimester should be vaccinated as soon as vaccine becomes available. Vaccination levels are still low in most adult populations in the United States and require more aggressive vaccination efforts.

The efficacy of inactivated influenza vaccine varies with the host's condition and the degree to which antigens in the vaccine match viruses that circulate during the following season. A high-dose inactivated vaccine consists of four times the hemagglutinin for each of the four strains compared with standard-dose vaccine. An inactivated adjuvanted vaccine contains standard doses of each of the four hemagglutinins but also contains MF59 as an adjuvant. Both the high-dose and adjuvanted vaccine are produced in eggs.

In recent years, the effectiveness of the vaccine has averaged about 30% for preventing laboratory-confirmed outpatient illness in persons 50 years and older and about 45% for preventing influenza-like illness in residents of long-term care facilities.[11] Protection often varies depending upon the type of influenza, and protection is higher with higher vaccine doses.[12] Live attenuated vaccine is licensed only for nonpregnant persons aged 2 through 49 years without underlying conditions that place them at high risk of complications from influenza. LAIV may be used for appropriately aged contacts of high-risk persons but is generally not recommended for contacts of severely immunosuppressed patients, such as patients with bone marrow transplants.

The high-dose and adjuvanted vaccines are recommended only for adults over age 65 years. Aside from LAIV, which is recommended only for persons ages 2 to 49 years, there is no preference for one vaccine over another for the general population. All influenza vaccines can be used in all adults provided they have no contraindications.

Influenza vaccination also reduces cardiovascular events. Vaccination efforts should begin as soon as the vaccine becomes available and should continue throughout the season. Peak influenza activity usually recurs in January or February, and influenza season continues through March.

Adverse Reactions

The most common side effect of inactivated vaccine is soreness at the injection site. Fever, malaise, and myalgia may begin 6 to 12 hours after vaccination and persist for 1 or 2 days, although such reactions are most common in children exposed to vaccine for the first time. The most common adverse events after live attenuated influenza vaccine in adults are runny nose, headache, and sore throat. Guillain-Barré syndrome may occur at a rate of about one case per 1 million doses.

MEASLES

Indications

Measles (Chapter 338) immunization is recommended for all persons born in or after 1957 without laboratory evidence of immunity, laboratory confirmation of prior disease, or documentation of prior appropriate vaccination. Most adults are considered to have been appropriately vaccinated if they received one dose of vaccine on or after their first birthday. However, adults who are at increased risk of exposure to measles or transmission of it (e.g., health care personnel, college students, international travelers) should receive a second dose if they did not get a second dose as children, unless they have serologically documented immunity, have laboratory confirmation of disease, or were born before 1957. Persons embarking on foreign travel should have received two doses of MMR vaccine or have other evidence of measles immunity as defined before. Persons born before 1957 are usually immune as a result of natural infection and do not require vaccination, although vaccination is not contraindicated if they are believed to be susceptible.

During educational institutional outbreaks of measles, all persons who have not received two doses or who lack other evidence of measles immunity should be vaccinated. Although measles vaccine can be administered only with mumps and rubella as MMR, individuals already immune to one or more of the components may receive MMR without harm.

Measles vaccine is contraindicated for pregnant persons on theoretical grounds, for persons with altered immunocompetence (except those with HIV infection who are not severely immunocompromised), and for persons with a history of severe allergic reaction (e.g., anaphylaxis) to a prior dose or to a vaccine component. Patients with anaphylactic reactions to eggs can be vaccinated without prior skin testing.

Adverse Reactions

MMR vaccine can cause fever (<15%), rash (5%), transient lymphadenopathy (20%), or parotitis (<1%). Febrile reactions, which usually are otherwise asymptomatic, generally occur 7 to 12 days after vaccination and persist for 1 or 2 days. MMR vaccination can rarely cause anaphylaxis, febrile seizures in children, thrombocytopenic purpura, transient arthralgia, and measles inclusion body encephalitis in persons with demonstrated immunodeficiencies.

MENINGOCOCCAL DISEASE

Three quadrivalent meningococcal vaccines are available against disease caused by serogroups A, C, W, and Y of *Neisseria meningitidis* (Chapter 274). One conjugate vaccine consists of each serogroup-specific polysaccharide covalently linked to 48 μg of diphtheria toxoid and is licensed for persons 9 months to 55 years of age. The second conjugate vaccine consists of the polysaccharides linked to CRM_{197} and is licensed for persons 2 months to 55 years of age. The third conjugate vaccine consists of the polysaccharides linked to tetanus toxoid and is licensed for persons 2 years old and older. The four serogroups in each vaccine account for approximately half of meningococcal disease cases in the United States, including in persons 11 years of age or older (Chapter 274). Conjugate vaccines induce immunologic memory and result in higher and more durable levels of high-avidity antibodies. The duration of immunity for MenACWY is estimated at between 3 and 5 years.

Two recombinant meningococcal serogroup B vaccines are licensed in the United States for persons 10 through 25 years of age. One vaccine (MenB-4C) contains three outer membrane proteins as well as protein-containing outer membrane vesicles, and the other (MenB-FHbp) contains two different alleles of the outer membrane protein (FHbp). Because of the low incidence of serogroup B meningococcal disease, evidence of vaccine effectiveness was inferred based on demonstration of immune response, as measured by serum bactericidal activity using human complement, against a small number of serogroup B strains.

Indications

Routine vaccination with MenACWY is recommended for all adolescents at 11 through 18 years of age, with a first dose administered at age 11 or 12 years and revaccination at age 16 years. For adolescents who receive a first dose between ages 13 and 15 years, a booster dose is recommended at age 16 to 18 years. Meningococcal vaccination is also recommended for unvaccinated and undervaccinated college freshmen who will live in dormitories, for military recruits, for persons at risk during a community outbreak attributable to a vaccine serogroup, and for persons who travel to or live in areas with hyperendemic or epidemic disease (e.g., the "meningitis belt" of sub-Saharan Africa, stretching from Mauritania to Ethiopia). For persons at ongoing increased risk of meningococcal disease (i.e., microbiologists with frequent exposure to *N. meningitidis* in culture and persons with persistent complement component deficiencies, splenic dysfunction, asplenia, or HIV infection), MenACWY vaccination is also recommended, with revaccination every 5 years.

MenB vaccines are recommended for a narrower group of persons at increased meningococcal disease risk compared with MenACWY: persons with persistent complement component deficiencies (including inherited or chronic deficiencies in C3, C5 to C9, properdin, factor D, factor H, or who are taking eculizumab or ravulizumab); anatomic or functional asplenia; microbiologists routinely exposed to isolates of *N. meningitidis;* and those at increased risk because of a serogroup B meningococcal disease outbreak. MenB vaccines are not recommended routinely for first-year college students in residence halls, military recruits, or international travelers. A MenB vaccine series may be administered on the basis of shared vaccine decision making to adolescents and young adults aged 16 to 23 years to provide short-term protection against most strains of serogroup B meningococcal disease. The preferred age for MenB vaccination is 16 to 18 years.

Both MenB-4C and MenB-FHbp are administered in a two-dose series for healthy individuals. For individuals at increased risk of serogroup B meningococcal disease, one of the MenB vaccines (MenB-FHbp) is recommended in a three-dose series. For individuals at continued increased risk, a booster dose is recommended 1 year after completion of the primary series and then every 2 to 3 years thereafter based on continuing risk. For persons at risk in an outbreak who may have received previous doses of MenB vaccine, a booster dose may be given 1 year after the primary series or as little as 6 months after the primary series if recommended by public health officials. MenB vaccines are not interchangeable, and the same brand of MenB vaccine should be used for all primary series doses and the booster doses. The current low prevalence of disease, coupled with lack of data for making policy recommendations for MenB vaccines, resulted in ACIP's determining insufficient evidence exists to make a routine public health recommendation that all adolescents be vaccinated

with MenB vaccine. Given the seriousness of meningococcal disease and the availability of licensed vaccines, ACIP agreed sufficient evidence exists to encourage shared clinical decision making about MenB vaccination for adolescents and young adults who are not otherwise at increased risk for serogroup B meningococcal disease.

Adverse Reactions

The most common adverse reactions to MenACWY are injection site reactions and systemic symptoms, such as headache and malaise, which generally persist for 1 or 2 days. An excess risk of Guillain-Barré syndrome was initially reported after vaccination with one of the three MenACWY vaccines but has not been confirmed in subsequent studies.

Injection site reactions are common with MenB vaccines. The most common systemic adverse reactions observed within the 7 days after receipt of MenB vaccines are fatigue, headache, and myalgia.

MUMPS

Indications

Mumps (Chapter 340) vaccine is indicated for all persons without evidence of immunity. For most adults, such evidence consists of a prior history of vaccination on or after the first birthday, laboratory evidence of immunity, or laboratory confirmation of disease. For adults at high risk, including health care personnel, international travelers, and students at post–high school educational institutions, two doses of mumps vaccine constitute acceptable evidence of immunity. Most persons born before 1957 can be considered immune as a result of natural infection, although vaccination is not contraindicated if such persons are thought to be susceptible. Persons who were previously vaccinated with two doses of a mumps-containing vaccine and who are identified by public health officials as at increased risk for mumps because of a mumps outbreak should receive a third dose of a mumps-containing vaccine to improve protection against mumps disease and related complications.

Mumps vaccine is contraindicated for pregnant persons on theoretical grounds, for persons with moderate to severe acute febrile illnesses, and for persons with altered immunocompetence. When it is combined with measles vaccine, it may be given to persons with asymptomatic HIV infection and considered for persons with symptomatic infection if they are not severely immunocompromised. Patients with anaphylactic reactions to eggs can be vaccinated without skin testing.

Adverse Reactions

Adverse events after the vaccine strain used in the United States are uncommon but include fever, parotitis, and allergic reactions. Thrombocytopenic purpura has been reported rarely after MMR (see also, Measles, Adverse Reactions).

PERTUSSIS

Each of the two vaccines licensed for boosting immunity to pertussis (Chapter 289) in adults is combined with tetanus and diphtheria toxoids as Tdap, which has a lower content of pertussis antigens compared with the childhood pertussis-containing vaccines (DTaP). Boostrix (GlaxoSmithKline), which is licensed for adolescents and adults 10 years of age and older, contains three pertussis antigens—toxoid (PT), filamentous hemagglutinin (FHA), and pertactin (PRN). Adacel (Sanofi Pasteur), which is licensed for 10 through 64 years of age, contains five pertussis antigens: PT, FHA, PRN, and two fimbriae. Both vaccines, when they are administered to previously vaccinated adolescents and adults, induce serologic responses that are comparable to those induced with effective childhood vaccination.

Indications

A single dose of Tdap is indicated for all adolescents at 11 to 12 years of age. All adults who have not received Tdap should receive it regardless of the interval since their last tetanus or diphtheria toxoid–containing vaccine. Tdap can be given at any interval after a prior Td. All pregnant persons should receive one dose of Tdap vaccine during each pregnancy, optimally early in the period between 27 and 36 weeks of gestation to maximize maternal antibody response and passive antibody transfer to the infant. Persons not vaccinated during pregnancy should receive Tdap postpartum if they have never previously been vaccinated with it. With the exception of pregnant persons, booster doses of Tdap are not recommended. However, in any circumstance in which a tetanus-toxoid vaccine is indicated generally, Tdap may substitute for Td, unless there is a contraindication to the pertussis component.

Adverse Reactions

Adverse events, usually local reactions, are similar to the adult preparation of Td alone compared with Tdap vaccine (see the section on tetanus and diphtheria later).

PNEUMOCOCCAL DISEASE

Pneumococcal polysaccharide vaccine (PPSV23) consists of purified polysaccharide capsular antigens from 23 types of *Streptococcus pneumoniae* (Chapter 268). Most adults, including elderly patients and those with alcoholic cirrhosis and diabetes mellitus, have a two-fold or greater rise in type-specific antibodies within 2 to 3 weeks of vaccination. Vaccination is approximately 60% effective against invasive pneumococcal disease, but its efficacy against pneumonia in high-risk populations, such as patients with alcoholic cirrhosis or Hodgkin disease, is not clear.[A9]

Pneumococcal conjugate vaccines (PCV15) contains conjugated capsular antigen from the serotypes for which the previously recommended PCV13 is protective, plus serotypes 22F and 33F. PCV20 contains conjugated capsular antigen from the serotypes for which the previously recommended PCV13 is protective, plus serotypes 8, 10A, 11A, 12F, 15B, 22F, and 33F.

Three pneumococcal vaccines are currently recommended for all adults ages 65 years and older. For patients who are PCV13-naïve, clinicians may choose PCV20 or choose PCV15 followed by PPSV23 a year later. Adults ages 19 through 64 years who have a high-risk condition for invasive pneumococcal disease (asthma, diabetes mellitus, cirrhosis, cerebrospinal fluid leaks, splenic dysfunction or anatomic asplenia, Hodgkin disease, lymphoma, multiple myeloma, chronic renal failure, nephrotic syndrome, immunosuppression, HIV infection, cigarette smoking) and who previously have not received PCV13 should receive either a dose of PCV20 or PCV15 followed by PPSV23 8 weeks to a year later.

Indications

The preponderance of information supports the use of pneumococcal vaccines in high-risk populations, including all persons 65 years and older and persons 19 years or older with conditions (Table 15-2). Special efforts should target hospitalized patients. Approximately two thirds of patients who are admitted later with pneumococcal disease had been hospitalized for other reasons within the preceding 5 years.

Because immunity may decrease 5 years or more after initial vaccination with PPSV23, a single booster dose of PPSV23 should be considered at that time for adults at highest risk of disease (such as asplenic patients) and for adults who lose antibody rapidly (such as patients with nephrotic syndrome or renal failure). Persons 65 years or older who received a dose more than 5 years earlier when they were younger than 65 years also should be revaccinated. Because of the rarity of severe reactions in revaccinated patients, persons with indications for vaccination but with unknown histories of prior vaccination should be vaccinated.

Adverse Reactions

Local reactions to PPSV23 are frequent, but less than 3% of vaccinees experience severe local reactions or systemic symptoms such as fever and malaise. Severe events, such as anaphylaxis or Arthus-like reactions at the site of injection, are rare. PCV13 reactions include pain, redness, and swelling at the injection site; limitation of movement of the injected arm; fatigue; and headache.

POLIOMYELITIS

Since 2000, inactivated poliovirus vaccine (IPV) has replaced the live attenuated oral poliovirus vaccine (OPV) in the United States because OPV vaccine caused about eight to nine polio cases per year in the United States among recipients or their contacts (Chapter 349). Trivalent OPV containing types 1, 2, and 3 has been replaced by bivalent OPV containing types 1 and 3 in all countries using OPV. In addition, there is a recommendation that all countries should include at least one dose of IPV in their immunization schedules.

Indications

Routine vaccination of persons 18 years of age or older is not recommended. If adults who are unvaccinated, are incompletely vaccinated, or have unknown vaccination status travel to areas where wild poliovirus is endemic or epidemic, they should receive a series of three doses: two doses of IPV administered at an interval of 4 to 8 weeks, with a third dose administered 6 to 12 months after the second. If three doses of IPV cannot be administered, alternatives include the following: three doses of IPV administered 4 weeks or more apart; two doses of IPV administered 4 weeks or more apart if less than 8 weeks remain before protection is needed; and, if less than 4 weeks remain before protection is needed, a single dose of IPV. If fewer than three doses are administered, the remaining doses needed to complete a three-dose

series should be administered when feasible, at the intervals recommended, especially if the person remains at increased risk for poliovirus exposure.

As a precaution, adults (≥18 years of age) who are traveling to areas where poliomyelitis cases are occurring and who have received a routine series with either IPV or OPV in childhood should receive another dose of IPV before departure. For adults, available data do not indicate the need for more than a single lifetime booster dose with IPV.

Adverse Reactions

Minor local reactions (pain, redness) commonly occur after IPV. Because IPV contains trace amounts of streptomycin, polymyxin B, and neomycin, allergic reactions may occur in persons allergic to these antibiotics.

RABIES

Two inactivated rabies vaccines are licensed in the United States. Human diploid cell vaccine (HDCV), which is prepared from the Pitman-Moore strain of rabies virus, also contains small amounts of neomycin sulfate, albumin, and phenol red indicator. The purified chick embryo cell vaccine (PCECV), which is prepared from the Flury LEP rabies virus strain, also contains small amounts of polygeline, human serum albumin, potassium glutamate, and sodium ethylenediamine tetra-acetic acid (EDTA). Both vaccines are given intramuscularly.

Indications

Rabies (Chapter 383) vaccine is indicated for preexposure prophylaxis of high-risk persons, including animal handlers, selected laboratory and field workers, and persons traveling for more than 1 month to areas where rabies is a constant threat. For both rabies vaccines, the preexposure regimen consists of two 1-mL intramuscular injections on days 0 and 7, followed by a titer at regular intervals depending on risk. If the titer is negative, a booster dose should be administered. Adults at intermediate risk (veterinarians, travelers) may receive a third dose of vaccine instead of a titer, provided that it is administered between 21 days through 3 years following the first dose.[13] Postexposure treatment depends on prior exposure to vaccine (Chapter 383). Persons being treated for the first time should be given human rabies immune globulin as well as four doses of vaccine at days 0, 3, 7, and 14.

Adverse Reactions

Local reactions (e.g., pain at the injection site, redness, swelling, and induration) are common after both rabies vaccine preparations. Hypersensitivity reactions have been reported in up to 6% of persons after booster doses of HDCV.

RUBELLA

Indications

One dose of rubella vaccine (Chapter 339) is indicated for adults born in 1957 or later without evidence of immunity and for women of any age who lack evidence of immunity and who are considering becoming pregnant. Persons without a prior history of vaccination on or after the first birthday, laboratory evidence of immunity, or laboratory confirmation of disease should be considered as lacking evidence of immunity. A single dose of vaccine is 95% or more effective. Many persons receive two doses of rubella vaccine by the two-dose schedule of MMR.

Rubella vaccine is contraindicated for persons with moderate to severe acute illnesses and persons with reduced immunocompetence. When it is given with measles vaccine, it may be administered to persons with asymptomatic HIV infection and considered for symptomatic persons who are not severely immunocompromised. Rubella vaccine is grown in human diploid cells and can be administered without problems to persons with egg allergies.

Adverse Reactions

Follow-up of pregnant persons who had no evidence of immunity and who received rubella vaccines within 3 months of the estimated date of conception showed no evidence of defects compatible with congenital rubella syndrome in their offspring. Nevertheless, vaccine is contraindicated in pregnant persons on theoretical grounds, and conception should be delayed for 1 month after rubella vaccination.

Arthralgia develops among about 25% of nonimmune postpubertal females after vaccination with rubella vaccine. Symptoms generally begin 1 to 3 weeks after vaccination, usually are mild, persist for about 2 days, and rarely recur. These symptoms are less common in postpubertal males compared with females. Other infrequent adverse events include transient peripheral neuritis and pain in the arms and legs. Thrombocytopenic purpura is rare when rubella vaccine is administered as MMR.

TETANUS AND DIPHTHERIA

Tetanus (Chapter 271) toxoid is one of the most effective immunizations, with more than 95% protection after a primary series of three doses. In persons aged 7 years or older, it should always be used in combination with diphtheria (Chapter 272) toxoid (Td), which is more than 85% effective in preventing disease. Combinations that also include pertussis antigens (Tdap) are preferred to Td for routine immunization of adolescents and adults who have yet to receive Tdap as well as for pregnant persons (for whom Tdap is recommended during every pregnancy). Doses need not be repeated if the schedule is interrupted. A booster dose of Tdap or Td is recommended every 10 years.

Indications

After a wound, persons of unknown immunization status or persons who have received fewer than three doses of tetanus toxoid should receive a dose of Tdap or Td regardless of the severity of the wound. Td also is indicated for persons who have previously received three or more doses if more than 10 years has elapsed since the last dose, in the case of clean and minor wounds, and if more than 5 years has elapsed for all other wounds. However, the benefit of an adult tetanus or diphtheria booster is probably very, very small.[14] Persons who have never received a dose of Tdap should receive it instead of Td for wound management. Tetanus immune globulin should be administered simultaneously at a separate site to persons who have wounds that are not clean and minor if they have not previously received at least three doses of toxoid.

Adverse Reactions

Most reactions to Td consist of local inflammation and low-grade fever. Exaggerated local (Arthus-like) reactions, with extensive painful swelling, often from shoulder to elbow, are occasionally reported 2 to 8 hours after receipt of a diphtheria- or tetanus-containing vaccine, particularly in persons who have received frequent doses of diphtheria or tetanus toxoid. Severe systemic reactions, such as generalized urticaria, anaphylaxis, Guillain-Barré syndrome, and other neurologic complications, rarely have been reported after receipt of tetanus toxoid.

VARICELLA: CHICKENPOX

A single dose of live attenuated varicella vaccine (Oka strain), which can be combined with MMR vaccine, protects 70 to 90% of recipients against any disease and more than 95% of recipients against severe disease, but a two-dose schedule is recommended. Whether immunity wanes with increasing time after vaccination is unclear. Use of vaccine has been associated with dramatic decreases in the incidence of varicella.

Indications

Persons 13 years or older without evidence of immunity to varicella should receive two doses at least 4 weeks apart. Evidence of immunity to varicella for adults includes documentation of two doses of varicella-containing vaccine (varicella or MMRV) at least 28 days apart, laboratory evidence of immunity or laboratory confirmation of disease, birth in the United States before 1980, or diagnosis or verification of a history of varicella or herpes zoster disease by a health care provider. Serologic screening of adults in some situations may be cost-effective, provided that identified susceptible adults are vaccinated. Serologic testing is not indicated after vaccination. The vaccine is contraindicated in persons who are immunocompromised, persons with anaphylactic allergies to vaccine components, and pregnant persons. Postexposure vaccination within 3 days of exposure can reduce the likelihood of symptomatic infection by about two-thirds. The varicella vaccine formulation marketed in the United States is temperature sensitive, so it must be stored at −50°C to −15°C to retain potency.

Adverse Reactions

The most common side effect is soreness at the injection site, which is reported in 25 to 35% of recipients 13 years or older. Varicella-like rashes at the injection site (median of two lesions) have been reported in 3% of recipients in this age group after the first dose and in 1% after the second dose. Nonlocalized rashes with a median of five lesions have been reported in 5.5% of recipients after the first dose and in 0.9% after the second dose. Although the vaccine virus can cause herpes zoster (shingles), especially in children, the incidence is substantially lower than would be expected after natural varicella (Chapter 346). More severe events in temporal relation to the vaccine have been reported rarely, but a causal relationship has not been established. Transmission of vaccine virus to a contact is extremely rare and probably occurs only from vaccinees in whom a varicella-like rash developed.

VARICELLA-ZOSTER

Recombinant zoster vaccine (RZV), a subunit vaccine containing varicella-zoster virus glycoprotein E with the $ASO1_B$ adjuvant system, is about 97% effective for the prevention of herpes zoster in persons ages 50 to 69 years and about 91% effective in persons aged 70 years and older.[15] This is the only zoster vaccine available in the United States.

Indications

Recombinant zoster subunit vaccine (RZV) is recommended for all adults ages 50 years and older and for adults ages 18 through 49 years who are immunosuppressed. The vaccine is recommended even in adults who previously received live zoster vaccine or had herpes zoster, and it is not necessary to elicit a history of varicella or to test for varicella immunity before administering RZV. The vaccine is administered intramuscularly as two doses separated by 2 to 6 months.[16]

Adverse Reactions

Local reactions (erythema, pain or tenderness, and swelling at the injection site) are common. Moderate or severe local reactions occur in about 10% of RZV vaccine recipients, and moderate or severe systemic reactions also occur in about 10%. If an individual has a reaction to the first dose, it does not affect their likelihood of a reaction to the second dose.

VACCINES INTENDED PRIMARILY FOR INTERNATIONAL TRAVELERS

Evaluation of people before travel should include a review and provision of routine vaccines recommended on the basis of age and other individual characteristics. Recommendations for specific vaccines related to travel will depend on itinerary, duration of travel, and host factors. Detailed recommendations are available at www.cdc.gov/travel.[17]

CHOLERA

Indications

Cholera (Chapter 278) vaccine is indicated for adult travelers (aged 18 to 64 years) from the United States to areas of the world with endemic or epidemic cholera caused by toxigenic *Vibrio cholerae* O1 within the past year (https://wwwnc.cdc.gov/travel/). Lyophilized CVD 103-HgR (Vaxchora, PaxVax) is a single-dose, live attenuated oral cholera vaccine. Its efficacy against severe diarrhea (defined as fecal output >3 L/24 hours) after oral toxigenic *V. cholerae* O1 challenge is estimated to be 90% at 10 days after vaccination and 80% at 3 months after vaccination.[18] There is no recommendation for use of booster doses at this time.

Adverse Reactions

Available safety data indicate no harms except for a slightly elevated risk for mild diarrhea among vaccine recipients.

JAPANESE ENCEPHALITIS

Indications

Japanese encephalitis (Chapter 352) vaccine is indicated primarily for travelers to Asia who will spend a month or longer in endemic areas during the transmission season, especially if travel will include rural areas. In all instances, travelers should be advised to take personal precautions to reduce exposure to mosquito bites. An older vaccine was reported to be 80 to 91% effective in preventing clinical disease, and the current whole virus inactivated vaccine (Ixiaro, Intercell Biomedical) was licensed on the basis of comparable immunogenicity. The primary series consists of two 0.5-mL doses given intramuscularly on days 0 and 28, for patients 2 months and older, with the second dose administered at least 1 week before travel. If the primary series was administered more than 1 year previously, a booster dose may be given before the next potential exposure to the virus. The FDA has approved an alternate 0- and 7-day schedule for persons 18 years old and older.

Adverse Reactions

Headache, myalgia, and local reactions (pain and tenderness) occur in more than 10% of vaccinees. However, the incidence rates of these events were similar to those in a comparison group that received a placebo with aluminum hydroxide.

TYPHOID

Indications

The cumulative efficacy at 2.5 to 3.0 years for the live attenuated Ty21a oral vaccine is about 50%, whereas the cumulative efficacy at 2.5 to 3.0 years for the capsular polysaccharide vaccine is about 55%. Typhoid (Chapter 284) vaccine is indicated primarily for travelers to areas where the risk of prolonged exposure to contaminated food and water is high. Because the vaccine is not always effective, food and water precautions are still essential. The vaccine also may be considered for family or other intimate contacts of typhoid carriers and laboratory workers who work with *Salmonella* Typhi. The capsular polysaccharide vaccine is approved for persons 2 years old and older. The live attenuated Ty21a oral vaccine is approved for persons ages 6 years and older. For adults and children 6 years and older, either of the vaccines may be used. For Ty21a, one enteric-coated capsule is taken every other day for four doses. Alternatively, a single dose of the ViCPS vaccine may be given. The duration of protection with Ty21a is not known; repetition of the primary series is recommended every 5 years for persons at risk. Boosters are recommended every 2 years for the ViCPS vaccine if persons continue to be at risk. The ViCPS vaccine can be given to children as young as 2 years.

Adverse Reactions

Fever and headache may occur after receipt of typhoid vaccines. Stomach pain, nausea, and rash are rarely observed.

YELLOW FEVER

Indications

Yellow fever (Chapter 351) occurs only in areas of South America and Africa. Vaccination with a single dose of the live attenuated 17D strain of virus confers protection to almost all recipients for at least 10 years. For most persons only a single dose is recommended. However, a booster dose is recommended every 10 years for at-risk laboratory personnel and certain previously vaccinated travelers (pregnant persons before travel to at-risk areas; hematopoietic stem cell transplant recipients vaccinated before transplant; HIV-infected persons; and travelers who will be in a higher-risk setting based on season, location, activities, and duration of their travel, such as travelers who plan to spend a prolonged period in endemic areas or those traveling to highly endemic areas such as rural West Africa during peak transmission season or an area with an ongoing outbreak).

Yellow fever vaccine should not be given to immunocompromised persons or persons with anaphylactic allergies to eggs. The vaccine is contraindicated in pregnant persons on theoretical grounds, although pregnant persons who must travel to a high-risk area may be vaccinated.

Adverse Reactions

Adverse reactions (fever, aches, and soreness, redness, or swelling where the injection was given) occur in up to 25% of vaccinees. Anaphylaxis has been reported in 0.8 to 1.8 persons per 100,000 doses of vaccine distributed. A rare syndrome (0.25 case per 100,000 doses distributed) of multiple organ system failure with high rates of mortality called viscerotropic disease has been reported, primarily among older adults and persons who have undergone thymectomy or have severe thymic dysfunction. Meningoencephalitis, Guillain-Barré syndrome, acute disseminated encephalomyelitis, and bulbar palsy have been reported in 1 per 125,000 doses and are more common in older vaccinees. In patients 60 years and older who are going to spend time in yellow fever–endemic zones, yellow fever vaccine should be administered with caution and only after careful counseling.

VACCINES FOR POSSIBLE BIOTERRORISM AGENTS

ANTHRAX

Anthrax (Chapter 272) vaccine adsorbed (AVA) is prepared from a cell-free filtrate of a nonencapsulated strain of anthrax and contains many cell products, including protective antigen. Protective antigen is responsible for binding to cells, allowing transport of lethal factor and edema factor into host cells. A recombinant protective antigen (rPA) vaccine is in clinical trials.

Indications

Preexposure prophylaxis consists of a three-dose primary intramuscular schedule at 0 and 4 weeks and at 6 months, with booster doses at 12 and 18 months, followed by boosters every 3 years thereafter. Protective efficacy of an earlier form of the vaccine against cutaneous anthrax was 92.5%. Animal models suggest efficacy against inhalation anthrax. Preexposure vaccination is recommended for persons engaged in work involving exposure to high concentrations of *Bacillus anthracis* or in activities with high potential for aerosol production. Vaccine is recommended in conjunction with antibiotics

for postexposure prophylaxis after exposure to aerosolized *B. anthracis* spores. The recommended regimen is three doses of AVA administered at 0, 2, and 4 weeks, combined with 60 days of antibiotics, which should be continued for at least 14 days after the third dose of vaccine (Chapter 272).

Adverse Reactions

The most common adverse events are local reactions, including subcutaneous nodules, which are thought to be due to the deposition of the aluminum-containing adjuvant in subcutaneous tissue. These adverse events are less common with intramuscular injections than with subcutaneous injections.

SMALLPOX

Two licensed vaccines are available for prevention of smallpox. ACAM 2000 vaccine uses live vaccinia virus, an orthopox virus that is distinct from variola and cowpox viruses and that provides cross-protection from smallpox. Smallpox vaccine is close to 100% effective when it is administered properly with a bifurcated needle. The skin usually does not need any special preparation. If alcohol is used for cleaning, the skin should be allowed to dry before vaccination to avoid inactivation of the vaccine. The needle is held perpendicular to the skin with 15 punctures for all vaccinees, made rapidly with enough vigor to ensure that a trace of blood appears within 15 to 20 seconds. With a primary take, the vaccination site should become reddened and pruritic within 3 or 4 days after vaccination; a large vesicle with a red areola forms and becomes pustular by 7 to 11 days. The lesion scabs by the third week.

Jynneos vaccine is a live, nonreplicating vaccinia vector vaccine, which uses the modified vaccinia Ankara strain. It is approved for persons ages 18 years and older for prevention of smallpox and/or monkeypox infection. Its efficacy is inferred through comparison of immunogenicity with ACAM 2000. It is administered as a subcutaneous injection in two doses 4 weeks apart.

Indications

The vaccine is indicated for persons who work with orthopox viruses. To increase preparedness for a smallpox attack, vaccination is often recommended for persons who will serve on public health or health care response teams. The duration of immunity is unclear. Revaccination is recommended at least every 10 years for persons who continue to be at risk. Contraindications for both vaccines include a history of severe allergic reactions (e.g., anaphylaxis) to a previous dose of vaccine or to a component. Immunosuppression is a contraindication to the ACAM 2000 live virus vaccine. Other contraindications to ACAM 2000 include history or presence of eczema, other chronic or exfoliative skin conditions, and pregnancy in the patient or a close household or other contact. Persons who are younger than 1 year, are breast-feeding, or have allergies to vaccine components should not be vaccinated. Because of reports of postvaccination cardiac events, vaccination should be deferred in persons with ischemia or other severe heart diseases or persons at high risk for ischemic heart disease events (https://www.cdc.gov/smallpox/clinicians/vaccination.htm). In the event of exposure to variola, the risk of disease outweighs any contraindications. Should variola be introduced into a community, vaccination would be indicated for all exposed persons and their close contacts to prevent further spread, and recommendations for more widespread vaccination would have to be evaluated on a case-by-case basis.

Adverse Reactions

For ACAM 2000, fever is the most common adverse event. Other more serious complications include eczema vaccinatum, which is a local or disseminated vaccinia infection in persons with a history of eczema or other exfoliative dermatitis; vaccinia necrosum, which occurs in immunocompromised persons; autoinoculation, especially of the eye, which can cause keratitis and scarring; generalized vaccinia; myopericarditis; and encephalitis. The risk for death from vaccinia is about one case per 1 million primary vaccinations. The most common adverse events to Jynneos include local reactions, myalgia, and headache.

EBOLA

Ervebo is a live attenuated vector vaccine with vesicular stomatitis virus as the vector with the gene encoding the glycoprotein of Ebola strain Zaire ebolavirus (Chapter 351). It is administered as a single intramuscular (IM) dose.

Indications

Ervebo is recommended for persons 18 years old and older who are responders to an outbreak of Ebola or who work in federally designated Ebola treatment centers in the United States. Additionally, vaccine is recommended for persons who work in biosafety level 4 facilities in the United States.

Adverse Reactions

The most common adverse reactions include local reactions, headache, and fever. Arthralgia and arthritis also occur, particularly in women and persons with a past history of arthritis. History of severe allergic reaction (e.g., anaphylaxis) to a previous dose of or to a component of the vaccine is a contraindication. After receiving a dose of vaccine, recipients should avoid kissing or sharing razors, eating utensils, toothbrushes, drinking cups, or needles for 2 weeks. Vaccine recipients should avoid donating blood, contact with high-risk persons, or exposure of livestock to blood or body fluids for 6 weeks. Barrier methods for sexual interaction should be used for 2 months.

OTHER AGENTS

Other organisms or products that have been considered potential bioterrorism threats include plague (Chapter 288) and botulinum toxin (Chapter 271). Poisoning with botulinum toxin can be treated with a trivalent antitoxin available from the Centers for Disease Control and Prevention (see https://www.cdc.gov/laboratory/drugservice/formulary.html). An experimental heptavalent botulinum toxoid can be obtained from the Centers for Disease Control and Prevention for laboratory workers at high risk for exposure to toxin. Preexposure vaccination is not warranted or feasible for the general population.

16 PRINCIPLES OF OCCUPATIONAL AND ENVIRONMENTAL MEDICINE

JUDITH GREEN-MCKENZIE

Occupational and environmental medicine is a multidisciplinary field that focuses on how to recognize, diagnose, treat, and prevent injuries and illnesses that arise from exposures at work and in the environment, as well as to improve the health, well-being, and safety of employees, their families, and their communities, locally and globally.[1] Physicians in occupational and environmental medicine collaborate with employers, safety personnel, industrial hygienists, occupational health nurses, ergonomists, human resources specialists, labor union leaders, and others. They must also be conversant with how environmental exposures can lead to illness.

Physicians who specialize in occupational and environmental medicine may have a responsibility to the employer as well as the worker.[2] All physicians who assess the possibility of work-related injury or illness also must be cognizant of the regulatory environment affecting their work.

for postexposure prophylaxis after exposure to aerosolized *B. anthracis* spores. The recommended regimen is three doses of AVA administered at 0, 2, and 4 weeks, combined with 60 days of antibiotics, which should be continued for at least 14 days after the third dose of vaccine (Chapter 272).

Adverse Reactions

The most common adverse events are local reactions, including subcutaneous nodules, which are thought to be due to the deposition of the aluminum-containing adjuvant in subcutaneous tissue. These adverse events are less common with intramuscular injections than with subcutaneous injections.

SMALLPOX

Two licensed vaccines are available for prevention of smallpox. ACAM 2000 vaccine uses live vaccinia virus, an orthopox virus that is distinct from variola and cowpox viruses and that provides cross-protection from smallpox. Smallpox vaccine is close to 100% effective when it is administered properly with a bifurcated needle. The skin usually does not need any special preparation. If alcohol is used for cleaning, the skin should be allowed to dry before vaccination to avoid inactivation of the vaccine. The needle is held perpendicular to the skin with 15 punctures for all vaccinees, made rapidly with enough vigor to ensure that a trace of blood appears within 15 to 20 seconds. With a primary take, the vaccination site should become reddened and pruritic within 3 or 4 days after vaccination; a large vesicle with a red areola forms and becomes pustular by 7 to 11 days. The lesion scabs by the third week.

Jynneos vaccine is a live, nonreplicating vaccinia vector vaccine, which uses the modified vaccinia Ankara strain. It is approved for persons ages 18 years and older for prevention of smallpox and/or monkeypox infection. Its efficacy is inferred through comparison of immunogenicity with ACAM 2000. It is administered as a subcutaneous injection in two doses 4 weeks apart.

Indications

The vaccine is indicated for persons who work with orthopox viruses. To increase preparedness for a smallpox attack, vaccination is often recommended for persons who will serve on public health or health care response teams. The duration of immunity is unclear. Revaccination is recommended at least every 10 years for persons who continue to be at risk. Contraindications for both vaccines include a history of severe allergic reactions (e.g., anaphylaxis) to a previous dose of vaccine or to a component. Immunosuppression is a contraindication to the ACAM 2000 live virus vaccine. Other contraindications to ACAM 2000 include history or presence of eczema, other chronic or exfoliative skin conditions, and pregnancy in the patient or a close household or other contact. Persons who are younger than 1 year, are breast-feeding, or have allergies to vaccine components should not be vaccinated. Because of reports of postvaccination cardiac events, vaccination should be deferred in persons with ischemia or other severe heart diseases or persons at high risk for ischemic heart disease events (https://www.cdc.gov/smallpox/clinicians/vaccination.htm). In the event of exposure to variola, the risk of disease outweighs any contraindications. Should variola be introduced into a community, vaccination would be indicated for all exposed persons and their close contacts to prevent further spread, and recommendations for more widespread vaccination would have to be evaluated on a case-by-case basis.

Adverse Reactions

For ACAM 2000, fever is the most common adverse event. Other more serious complications include eczema vaccinatum, which is a local or disseminated vaccinia infection in persons with a history of eczema or other exfoliative dermatitis; vaccinia necrosum, which occurs in immunocompromised persons; autoinoculation, especially of the eye, which can cause keratitis and scarring; generalized vaccinia; myopericarditis; and encephalitis. The risk for death from vaccinia is about one case per 1 million primary vaccinations. The most common adverse events to Jynneos include local reactions, myalgia, and headache.

EBOLA

Ervebo is a live attenuated vector vaccine with vesicular stomatitis virus as the vector with the gene encoding the glycoprotein of Ebola strain Zaire ebolavirus (Chapter 351). It is administered as a single intramuscular (IM) dose.

Indications

Ervebo is recommended for persons 18 years old and older who are responders to an outbreak of Ebola or who work in federally designated Ebola treatment centers in the United States. Additionally, vaccine is recommended for persons who work in biosafety level 4 facilities in the United States.

Adverse Reactions

The most common adverse reactions include local reactions, headache, and fever. Arthralgia and arthritis also occur, particularly in women and persons with a past history of arthritis. History of severe allergic reaction (e.g., anaphylaxis) to a previous dose of or to a component of the vaccine is a contraindication. After receiving a dose of vaccine, recipients should avoid kissing or sharing razors, eating utensils, toothbrushes, drinking cups, or needles for 2 weeks. Vaccine recipients should avoid donating blood, contact with high-risk persons, or exposure of livestock to blood or body fluids for 6 weeks. Barrier methods for sexual interaction should be used for 2 months.

OTHER AGENTS

Other organisms or products that have been considered potential bioterrorism threats include plague (Chapter 288) and botulinum toxin (Chapter 271). Poisoning with botulinum toxin can be treated with a trivalent antitoxin available from the Centers for Disease Control and Prevention (see https://www.cdc.gov/laboratory/drugservice/formulary.html). An experimental heptavalent botulinum toxoid can be obtained from the Centers for Disease Control and Prevention for laboratory workers at high risk for exposure to toxin. Preexposure vaccination is not warranted or feasible for the general population.

16 PRINCIPLES OF OCCUPATIONAL AND ENVIRONMENTAL MEDICINE

JUDITH GREEN-MCKENZIE

Occupational and environmental medicine is a multidisciplinary field that focuses on how to recognize, diagnose, treat, and prevent injuries and illnesses that arise from exposures at work and in the environment, as well as to improve the health, well-being, and safety of employees, their families, and their communities, locally and globally.[1] Physicians in occupational and environmental medicine collaborate with employers, safety personnel, industrial hygienists, occupational health nurses, ergonomists, human resources specialists, labor union leaders, and others. They must also be conversant with how environmental exposures can lead to illness.

Physicians who specialize in occupational and environmental medicine may have a responsibility to the employer as well as the worker.[2] All physicians who assess the possibility of work-related injury or illness also must be cognizant of the regulatory environment affecting their work.

ABSTRACT

Occupational and environmental medicine (OEM) combines clinical medicine, providing individual medical care, and public health, managing the health and safety of worker populations. A multidisciplinary field, it focuses on how to recognize, diagnose, treat, and prevent injuries and illnesses that arise from exposures at work and in the environment, as well as to improve the health, well-being, and safety of employees, their families, and their communities, locally and globally. OEM physicians collaborate with many stakeholders, including employers, safety personnel, industrial hygienists, occupational health nurses, ergonomists, human resources specialists, and labor union leaders. Workers' compensation is the main payer for work-related illnesses and injuries. The skillful OEM history clarifies the work relatedness of a condition. Appropriate medical management, using a graduated return to work process, employing accommodations where needed, will result in both reduced work disability and workers' compensation costs. OEM providers need to be knowledgeable about toxicological principles as they evaluate, monitor, and treat conditions such as heavy metal toxicity. They need to understand the impact and management of environmental factors such as exposure to hot working environments to prevent heat-related illness. Understanding the organization of work is paramount because lack of awareness or agency to effect change can create a fertile ground for burnout and expensive job turnover. Additionally, they need be cognizant of the surrounding regulatory environment where the Occupational Safety and Health Administration (OSHA) issues, promulgates, and enforces standards for workplace safety and health. These standards affect most workplaces, from medical institutions to construction, and are enforceable. Environmental standards such as The Emergency Planning and Community Right-to-Know Act are also important to consider. Emphasizing work and the environment as important social determinants of health, OEM has one of the highest satisfaction indices among medical specialties.

OCCUPATIONAL AND ENVIRONMENTAL MEDICINE REGULATORY ENVIRONMENT

Occupational and environmental medicine grew out of a necessity to provide protections for workers in the context of the heightened awareness about industrial accidents and exposures as well as the liability of employers for workplace injuries and illnesses. Its development has been embedded in an evolving regulatory environment, and the two together have led to improved occupational health outcomes.[3]

WORKERS' COMPENSATION

Workers' compensation is a "no-fault" system in which monetary compensation is provided to workers for medical and rehabilitation costs as well as lost wages related to illnesses or injuries that arose out of or during the course of employment, regardless of cause. Employers are held responsible for compensation, and the injured worker accepts the standard amount of permitted compensation. Workers' compensation is now the third largest source of support for disabled workers after Social Security and Medicare.

WORK-RELATED DISABILITY

Physicians and other providers may be asked to determine the extent of their patient's disability under the workers' compensation system. In general, disability is an inability or limitation in performing activities, roles, and tasks within a social or physical environment. Disability differs from impairment, which refers to an anatomic or functional abnormality or loss. Individuals with the same impairment may have different degrees of disability, which may vary depending on factors such as economic demand, educational factors, job description, and age. Workers' compensation defines four types of disability:

- *Temporary total disability:* Inability to work for a period, but recovery is expected. Lost wage (indemnity) benefits are paid to the worker while on disability.
- *Permanent total disability:* Inability to undertake gainful employment, and further treatment will not lead to recovery. Indemnity benefits are paid to the worker.
- *Temporary partial disability:* The worker can perform some work duties (modified duty) and can return to work if a suitable placement can be found.
- *Permanent partial disability:* Permanent loss of one or several functions. Work is possible but in a modified duty capacity or at a different job.

Maximal medical improvement or *permanency* is said to have occurred when an injured worker has recovered as much as they are likely to recover and have likely reached a stage of permanent disability. Although the condition may improve over time, the best decision must be made with the information at hand at the time.

If an employer provides modified duty that the employee can perform, then this option can reduce payment for lost wages (indemnity costs) and thus reduce the overall cost of workers' compensation. This approach also keeps the employee in the work culture, thereby easing the way to return to full-duty work, if and when achievable. In fact, most injured workers return to full-duty work.

APPROACH TO THE PATIENT

SALIENT FEATURES OF THE OCCUPATIONAL AND ENVIRONMENTAL MEDICINE HISTORY

Two simple initial questions during the history taking—"What is your job? and "Where do you work?"—can help clinicians ascertain whether work may play a role in the patient's present illness and past medical history. If the condition is work related, a directed occupational and environmental history is essential to document any relationship to work so as to establish the background for any future workers' compensation claim. Otherwise the worker may be denied workers' compensation if the case is not clearly presented, or may at least experience a delay in receiving such benefits.

When a workers' compensation claim is filed, the adjuster who reviews the case relies greatly on the provider's initial medical note to determine whether to accept the claim. The physician and document must query about the mechanism of the injury or the nature of the exposure to assess any potential work-relatedness. In addition to usual questions to explore an injury, additional information should be elicited for a work-related claim:

- Reason for visit: chief complaint, which will guide future questions
- Mechanism of injury: helps ascertain work-relatedness
- Age: can help estimate time to recovery
- Handedness (right/left): may affect modified duty assigned by the provider
- Place of work: to appraise type of work potentially available (e.g., options that the worker may be able to perform)
- Job title: may help determine if modified duty is necessary
- Description of job duties: helps determine how to design modified duty work
- Prior injuries: can help the clinician determine longevity at work (e.g., if the employee had similar prior surgery, the clinician can explore potential preventive measures with the employee and the employer)
- Whether others are injured similarly: may suggest population level prevention
- Comorbid conditions: can influence current and future injuries and return-to-work arrangements
- Social history: determine living arrangements and whether help at home or duties at home may affect recovery
- Is the employee currently working: may help infer severity of injury or illness, thereby informing return to work status (modified or full duty)

In addition to detailed questions exploring an exposure, the clinician should elicit information about:

- The nature of exposure: agent and place of exposure (work, home, community)
- A standard exposure history: such as with the Exposure Survey created by the Agency for Toxic Substance and Disease Registry (E-Fig. 16-1)
- A safety data sheet (SDS): contains physical data, potential hazards, and handling and safety precautions data on all the potential toxins at work
- Symptom temporality: to determine if symptoms improve away from work or in a different environment, as in occupational asthma compared with asthma that has environmental triggers (Chapter 75)
- Time of peak symptoms: helps with temporality if during work hours
- Duration of symptoms: recent or remote onset
- Organ system involved (e.g., skin manifestations may suggest an agent with direct contact)
- Type of personal protective equipment used: determine adequacy
- Current work duties: help assess degree of potential exposure
- Occupational history using a standard survey (see E-Fig. 16-1): to determine exposures from prior jobs (e.g., sensitizers such as diisocyanate or beryllium)
- Length of employment: potential for sustained exposure
- Similar symptoms in other employees: ascertain if presentation is unique
- Smoking history: may be synergistic for a respiratory agent
- Family history of allergy: to determine atopy

CLINICAL IMPLICATIONS

ACUTE INJURIES

In the United States, approximately three million nonfatal workplace injuries and illnesses are reported annually. Over 50% of these injuries require modified duty, job transfer, or time away from work. The most commonly reported injuries are sprains, strains, and tears; soreness or pain; cuts, lacerations, and punctures; bruises and contusions; and fractures (Table 16-1).[4] Fractures result in the most lost work days. Initial management is basic first aid followed by referral, as necessary, to emergency care or an appropriate specialist.

Eye injuries are common and may be prevented with the use of appropriate personal protective equipment, such as eye protection for healthcare personnel conducting a procedure where a splash from a body fluid is possible or the use of welding goggles to prevent photokeratoconjunctivitis in a welder.

CLINICAL SYNDROMES

Environmental and occupational hazards especially affect individuals who have underlying diseases, chronic health conditions, or habits that increase their risk. For example, individuals who smoke have a higher risk of developing more severe lung disease from occupational exposures (Chapter 81).

Occupational or environmental diseases may be difficult to distinguish from other diseases that cause similar symptoms or signs. For acute syndromes, proximal exposure to toxins, often with similar symptoms in others, is a helpful clue. For more recurrent symptoms, a cyclic pattern in which symptoms worsen on workdays and improve on days off, is helpful. For chronic symptoms, such as hepatic dysfunction or neurologic findings, a more long-standing work or environmental exposure or toxin should be considered, and such a link is more likely if multiple individuals are affected.

For potential exposure to heavy metals (Chapter 20), blood levels can be diagnostic. For other exposures, a trial of withdrawal followed by re-challenge can be very helpful when it can be safely implemented.

Taking an Exposure History

Exposure History Form

Date:

Part 1. Exposure Survey **Name:** **Address:**

Please select the appropriate answer. **Birth date:** **Sex (select one):** ○ Male ○ Female

1. Are you currently exposed to any of the following?

metals	○ no ○ yes
dust or fibers	○ no ○ yes
chemicals	○ no ○ yes
fumes	○ no ○ yes
radiation	○ no ○ yes
biologic agents	○ no ○ yes
loud noise	○ no ○ yes
vibration	○ no ○ yes
extreme heat	○ no ○ yes
extreme humidity	○ no ○ yes
extreme cold	○ no ○ yes

2. Have you been exposed to any of the above in the past? ○ no ○ yes

3. Do any household members have contact with metals, dust, fibers, chemicals, fumes, radiation, or biologic agents? ○ no ○ yes

If you answered *yes* to any of the items above, describe your exposure in detail–how you were exposed, to what you were exposed, how much, how often, and how long you were exposed?

4. Do you know the names of the metals, dusts, fibers, chemicals, fumes, or radiation that you are/were exposed to? ○ no ○ yes → If *yes*, list them below

5. Do you get the material on your skin or clothing? ○ no ○ yes

6. Are your work clothes laundered at home? ○ no ○ yes

7. Do you shower at work? ○ no ○ yes

8. Can you smell the chemical or material you are working with? ○ no ○ yes

9. Do you use protective equipment such as gloves, masks, respirator, or hearing protectors? ○ no ○ yes → If *yes*, list the protective equipment used

10. Have you been advised to use protective equipment? ○ no ○ yes

11. Have you been instructed in the use of protective equipment? ○ no ○ yes

E-FIGURE 16-1. Exposure History Form. PBBs = polybrominated biphenyls; PCBs = polychlorinated biphenyls; MDI = methylene diphenyl diisocyanate; TDI = toluene diisocyanate.

12. Do you wash your hands with solvents?	○ no	○ yes
13. Do you smoke at the workplace?	○ no	○ yes
at home?	○ no	○ yes
14. Are you exposed to secondhand tobacco smoke at the workplace?	○ no	○ yes
at home?	○ no	○ yes
15. Do you eat at the workplace?	○ no	○ yes
16. Do you know of any co-workers experiencing similar or unusual symptoms?	○ no	○ yes
17. Are family members experiencing similar or unusual symptoms?	○ no	○ yes
18. Has there been a change in the health or behavior of family pets?	○ no	○ yes
19. Do your symptoms seem to be aggravated by a specific activity?	○ no	○ yes
20. Do your symptoms get either worse or better at work?	○ no	○ yes
at home?	○ no	○ yes
on weekends?	○ no	○ yes
on vacation?	○ no	○ yes
21. Has anything about your job changed in recent months (such as duties, procedures, overtime)?	○ no	○ yes
22. Do you use any (such as herbs or natural supplements) alternative medicines?	○ no	○ yes
23. Have you or your child ever eaten non-food items such as paint, plaster, dirt, and/or clay?	○ no	○ yes
24. Do you know how to access the Safety Data Sheet (SDS) at your workplace?	○ no	○ yes

If you answered *yes* to any of these questions, please explain.

E-FIGURE 16-1, cont'd

Taking an Exposure History

Part 2. Work History

A. Occupational Profile

The following questions refer to your current or most recent job:

Job title:

Type of industry:

Name of employer:

Date job began:

Are you still working in this job? ○ yes ○ no

If *no*, date job ended?

Describe this job:

Fill in the table below listing all jobs you have worked including short-term, seasonal, part-time employment, and military service. Begin with your most recent job.

Dates of Employment	Job Title and Description of Work	Exposures*	Protective Equipment

*List the chemicals, dusts, fibers, fumes, radiation, biologic agents (i.e., molds or viruses), and physical agents (i.e., extreme heat, cold, vibration, or noise) that you were exposed to at this job.

Have you ever worked at a job or hobby in which you came in contact with any of the following by breathing, touching, or ingesting (swallowing)? If *yes*, please select beside the name.

- ☐ Acids
- ☐ Alcohols (industrial)
- ☐ Alkalies
- ☐ Ammonia
- ☐ Arsenic
- ☐ Asbestos
- ☐ Benzene
- ☐ Beryllium
- ☐ Cadmium
- ☐ Carbon tetrachloride
- ☐ Chlorinated naphthalenes
- ☐ Chloroform
- ☐ Chloroprene
- ☐ Chromates
- ☐ Coal dust
- ☐ Dichlorobenzene
- ☐ Ethylene dibromide
- ☐ Ethylene dichloride
- ☐ Fiberglass
- ☐ Halothane
- ☐ Isocyanates
- ☐ Ketones
- ☐ Lead
- ☐ Mercury
- ☐ Methylene chloride
- ☐ Nickel
- ☐ PBBs
- ☐ PCBs
- ☐ Perchloroethylene
- ☐ Pesticides
- ☐ Phenol
- ☐ Phosgene
- ☐ Radiation
- ☐ Rock dust
- ☐ Silica powder
- ☐ Solvents
- ☐ Styrene
- ☐ Talc
- ☐ Toluene
- ☐ TDI or MDI
- ☐ Trichloroethylene
- ☐ Trinitrotoluene
- ☐ Vinyl chloride
- ☐ Welding fumes
- ☐ X-rays
- ☐ Other (specify)

E-FIGURE 16-1, cont'd

B. Occupational Exposure Inventory *Please select the appropriate answer.*

1. Have you ever been off work for more than 1 day because of an illness related to work? ○ no ○ yes
2. Have you ever been advised to change jobs or work assignments because of any health problems or injuries? ○ no ○ yes
3. Has your work routine changed recently? ○ no ○ yes
4. Is there poor ventilation in your workplace? ○ no ○ yes
5. Has your workplace flooded? ○ no ○ yes
6. Is your workplace damp? ○ no ○ yes
7. Do you perform outdoor work? ○ no ○ yes

Part 3. Environmental History *Please select the appropriate answer.*

1. Do you live next to or near an industrial plant, commercial business, dump site, or nonresidential property? ○ no ○ yes
2. Which of the following do you have in your home?
   Please select those that apply.
   ☐ Air conditioner ☐ Air purifier ☐ Central heating (○ Gas ○ Oil) ☐ Gas stove
   ☐ Electric stove ☐ Fireplace ☐ Wood stove ☐ Humidifier
3. Have you recently acquired new furniture or carpet, refinished furniture, or remodeled your home? ○ no ○ yes
4. Have you weatherized your home recently? ○ no ○ yes
5. Are pesticides or herbicides (bug or weed killers; flea and tick sprays, collars, powders, or shampoos) used in your home or garden, or on pets? ○ no ○ yes
6. Do you (or any household member) have a hobby or craft? ○ no ○ yes
7. Do you work on your car? ○ no ○ yes
8. Have you ever changed your residence because of a health problem? ○ no ○ yes
9. Does your drinking water come from a private well? ○ no ○ yes
   City water supply? ○ no ○ yes
   Grocery store? ○ no ○ yes
   Other (specify) [ ] ○ no ○ yes
10. Approximately what year was your home built? [ ]
11. Does your food come from somewhere other than a grocery store? ○ no ○ yes
12. Do you live in a rural area? ○ no ○ yes
13. Do you live in a suburban area? ○ no ○ yes
14. Do you live in the city? ○ no ○ yes
15. Has your home flooded? ○ no ○ yes
16. Is your home damp? ○ no ○ yes

If you answered *yes* to any of these questions, please explain.

TABLE 16-1 COMMON OCCUPATIONAL MUSCULOSKELETAL INJURIES

ANATOMICAL LOCATION	INJURY
Neck and Back Injury	Acute back or neck pain Disk herniation
Shoulder	Acromioclavicular joint separation Adhesive capsulitis Brachial plexus neuropathy Impingement syndrome Labral tear Rotator cuff tear Rotator cuff tendinosis Shoulder dislocation Subacromial bursitis Supraspinatus tendinitis
Elbow	Anterior interosseous syndrome Elbow dislocation Elbow fracture Lateral and medial epicondylitis Olecranon bursitis Pronator syndrome Radial tunnel entrapment Ulnar collateral ligament injury Ulnar nerve entrapment at elbow
Hand	Carpal tunnel syndrome De Quervain tenosynovitis Dupytren contracture Mallet finger Radius fracture Scaphoid fracture Trigger finger Ulnar fracture Wrist sprain
Hip	Bursitis Labral tear Tendonitis
Knee	Anterior cruciate ligament injury Collateral ligament injury Knee pain Medial and lateral meniscal injury Patellofemoral pain Posterior cruciate ligament injury
Ankle	Fracture Inversion or inversion injury
Eye Injury	Cataract Chemical or thermal burn Corneal abrasion Foreign body Splash to eye of infectious fluid Trauma
Ear Injury	Hearing loss due to acoustic or physical trauma Ototoxic hearing loss Sensorineural noise induced hearing loss
Occupational Infections	Bloodborne pathogen exposures Hepatitis B and C Herpes B virus Human immunodeficiency virus Influenza virus Severe acute respiratory syndrome coronavirus 2 Tuberculosis
Occupational Skin Manifestations	Allergic dermatitis from allergens such as latex and chromate Bedbugs Infectious agents such as herpes simplex Irritant contact dermatitis from cleansers and solvents Scabies Skin cancer from arsenic or polycyclic aromatic hydrocarbons

Common Clinical Syndromes

Although environmental and occupational exposures can cause or exacerbate many clinical syndromes, certain syndromes are especially common or problematic (Table 16-2).

TABLE 16-2 COMMON OCCUPATIONAL AND ENVIRONMENTAL HEALTH CONDITIONS IN GENERAL PRACTICE

CONDITION	EXPOSURE SETTINGS	COMMENT
Asthma	Virtually any indoor or outdoor workplace	New-onset, recrudescent, or exacerbated asthma
Interstitial, parenchymal, and inflammatory lung disorders	Dusts, metals, and organic materials	All parenchymal disorders have one or more environmental causes
Cancers of the respiratory tract	Asbestos, radon, silica, combustion fumes, tars, and some metals	Smokers are more likely to be affected
Sensorineural hearing loss	Noise, metals, and solvents	High-frequency loss, especially in younger workers
Musculoskeletal disorders of trunk and limbs	Heavy or repetitive activities or postures	Cold, vibration, and work stress contribute
Upper airway irritation	Dust and fumes	More common in smokers and atopic persons
Nonspecific building-related illness	Office work	Must exclude *specific* causes
Dermatitis, allergic or irritant	Repeated exposure to unprotected skin	Work and environmental exposures should be considered in every case
Multiple chemical sensitivities	Any	Complication of adverse environmental exposure

From Cullen MR. Principles of occupational and environmental medicine. In: Goldman L, Schafer AI, eds. *Goldman-Cecil Medicine*, 26th ed. Philadelphia: Elsevier; 2020: Chapter 16.

Asthma

Numerous workplace antigens ranging from animal dander, to latex, to small molecules are responsible for as much as 20% of adult-onset asthma (Chapter 75). The temporal relationship of symptoms to work may be the only clue, and resolution after removal from the toxic environment is the only way to establish the diagnosis.

Chronic Lung Diseases

Coal workers' pneumoconiosis (Chapter 81), silicosis (Chapter 81), and chronic berylliosis can all resemble sarcoidosis (Chapter 83) on a chest radiograph, and all may exacerbate any underlying chronic obstructive pulmonary disease (Chapter 76).[5,6] Asbestosis (Chapter 81) resembles idiopathic pulmonary fibrosis (Chapter 80) except for its pleural involvement. Hypersensitivity pneumonitis (Chapters 80 and 81) occurs in agricultural settings or wherever microbes contaminate work materials. Bronchiolitis obliterans is seen in workers in facilities that produce microwave popcorn or coffee as a result of exposure to diacetyl or 2,3-pentanedione. Inorganic chemicals can cause allergic alveolitis.

Respiratory Cancers

Occupational exposure to coal dust, asbestos, silica, polyaromatic hydrocarbons, diesel exhaust, pitch, asphalt, radon, chromium, and formaldehyde have been implicated in lung cancer (Chapter 177), and their risks are synergistic with cigarette smoking. Asbestos is also the major risk factor for malignant mesothelioma (Chapters 86 and 177).

Sensorineural Hearing Loss

Noise is second only to aging as a cause of high-frequency sensorineural hearing loss (Chapter 394).[7] Hearing protection can mitigate or prevent hearing loss and is required for major occupational noise exposure. Exposure to ototoxic workplace chemicals, such as aniline dyes used commercially to dye fabric, also may lead to hearing loss.

Musculoskeletal Disorders

Low back pain (Chapter 369) is the most common work-related musculoskeletal complaint. In addition to usual care, workplace preventive measures are key.

Other chronic musculoskeletal injuries include carpal tunnel syndrome (Chapter 388), epicondylitis, and De Quervain tenosynovitis. Physical therapy and medications are often helpful, but modifying the causal work and leisure activities is a key intervention.

Skin Conditions

Erythematous rashes commonly are caused by workplace or other exposures to latex, plastics, irritating chemicals, heat pressure, or friction. Identification and elimination of the precipitant is critical. Allergy testing (Chapter 230) by a consultant is helpful in difficult cases.

Common Exposures

Thousands of toxins (Table 16-3) and other hazards can potentially cause or exacerbate a wide range of conditions, but certain basic principles and clinical approaches can guide the assessment of their role in causing signs or symptoms in individual workers. The major determinants of the risk for clinical disease are exposure and absorption, which together determine the dose of the toxin.

Sick Building Syndrome

The inability to provide safe heating, air-conditioning, and air exchange in indoor spaces can result in nonspecific symptoms such as headache, fatigue, cough, and even skin rashes in multiple occupants in the affected building.[8] Molds and other microbial materials may be the cause, but a specific irritant may not be discovered despite extensive testing. Remediation of identifiable sources usually alleviates the problem, but sometimes empirical cleaning or replacement of systems may be required.

Metals

Exposures to lead and arsenic (Chapter 20) are now uncommon in the workplace but have been associated with contamination of drinking water in the United States and globally. Mercury (Chapter 20) is found in large ocean fish. Manganese (Chapter 20) in welding fumes and various alloys can cause extrapyramidal Parkinson-like symptoms and autonomic dysfunction. Blood or urine levels are generally the best way to make the diagnosis.

Solvents, Organohalides, Herbicides, and Pesticides

Petroleum derivatives, which are commonly components of workplace and household products, are irritating and sometimes neurotoxic or hepatotoxic (Chapter 96). Dioxin, which is produced by the combustion of chlorine-containing materials, can cause soft tissue sarcomas (Chapter 187) and perhaps other cancers. Glyphosate, which had been a common herbicide, is associated with about a 40% increased risk of non-Hodgkin lymphoma (Chapter 171). Exposure to pyrethroid insecticides is associated with increased mortality.[9]

Particulate Matter

Ambient air pollution is a major contribution not only to lung disease but also to cardiovascular disease[10,11] and all-cause mortality.[12] Some estimates suggest that indoor and outdoor air pollution cause 6 to 7 million annual deaths worldwide, about two-thirds of which are attributable to outdoor pollution. Respiratory irritants include sulfur dioxide, and small particulate matter that may be laden with proinflammatory polyaromatic hydrocarbons, which especially result from burning wood, coal, or diesel fuel.

Water

In addition to toxins such as lead and arsenic, more than 800 million people worldwide consume unclean drinking water that can be contaminated with bacteria, nontuberculous mycobacteria, and protozoa. Such contaminated water causes about 3.75 million deaths worldwide each year.

Disease outbreaks attributable to water can result in serious acute, chronic illness as well as result in a fatality, especially if one is immunocompromised. Water contamination is not distributed evenly. It may depend on seasonality, for example, where enteric infection and water-related illnesses occur more commonly during the periods of rain abundance, as in areas where bimodal rainfall patterns are experienced. Besides climatic events, the degree of contamination can also depend on the number of pathogens present in the water source, how old and well maintained the system is, and whether the water quality is inspected regularly.

Molds and Dusts

Molds, with or without a detectable odor, often stimulate an allergic airway response[13] (Chapter 230), sometimes as part of a broader contamination of indoor air handling systems. Mineral dusts include silica,[14] fibrous glass, mineral wool, and other synthetic fibers.

Radiation

Radiation exposure is discussed in Chapter 18.

Global Warming and Climate Change

Please see Chapter 17.

OCCUPATIONAL SAFETY STANDARDS

The Occupational Safety and Health Administration (OSHA) issues, promulgates, and enforces standards for workplace safety and health. The National Institute of Occupational Safety and Health (NIOSH), which is part of the Centers for Disease Control and Prevention, does not have authority to set standards, but its reviews regarding chemicals, toxicology, and other hazards provide evidence to help inform the process of setting standards to protect workers' health and safety. These evidence-based standards were created to protect workers and are enforced through workplace inspections and penalties that are assessed for noncompliance. Even for hazards for which clear standards do not exist, the employer is required to protect employees from potentially dangerous exposures.

MEDICAL SURVEILLANCE

Medical surveillance is the systematic, ongoing monitoring of workers who have exposure or potential exposure to occupational hazards. This measurement and assessment then inform secondary prevention measures and the ability to evaluate the effectiveness of prevention strategies.

HIERARCHY OF CONTROLS

The hierarchy of hazard controls, developed through the National Institute of Occupational Safety and Health, is a 5-tiered system that describes the most to least robust ways by which workers can be protected from a hazard. First is elimination, such as banning dichlorodiphenyltrichloroethane (DDT) use in agriculture. Next is substitution, such as using sesquisulfide in lieu of white phosphorus in matches, thereby successfully eliminating jawbone necrosis in workers. Third is the use of engineering controls to eliminate the hazard, as in using safety devices to reduce needlestick exposures in health care personnel. Fourth are administrative controls, such as social distancing to reduce the spread of coronavirus-19 (COVID-19) infection. Finally is the use of personal protective equipment, such as hearing protection to reduce noise exposure, when the hazard itself cannot be eliminated.

ENVIRONMENTAL MEDICINE

Physicians and other providers may be called upon to understand and manage medical concerns that arise from environmental exposures.[15] Tasks may include conducting a risk assessment, managing and communicating risk, making recommendations about possible human health effects, and assessing, understanding, and interpreting regulatory issues. The severity and urgency of environmental issues, such the adverse ramifications of a changing climate (Chapter 17) or environmental justice (e.g., neighborhoods being differentially affected by toxic waste), may vary geographically but remain major challenges. Being able to elicit a detailed environmental history may help reveal presenting diagnoses. Examples include a cardiac event precipitated by exposure to particulate matter 2.5 ($PM_{2.5}$) air pollution, heat-related illness from working in a hot environment without acclimatization or with inadequate access to shade and/or hydration, or a vector-borne disease (e.g., Lyme disease) in an area where the organism was not previously found but has emerged because of climate change.

ENVIRONMENTAL STANDARDS

Key statutes to address these environmental hazards include:

- The Resource Conservation and Recovery Act, which created the framework for the proper management of hazardous and nonhazardous solid waste.
- The Comprehensive Environmental Response, Compensation, and Liability Act, which established the federal Superfund program in 1980 to clean up uncontrolled or abandoned hazardous waste sites as well as accidents, spills, and other emergency releases of pollutants and contaminants into the environment.
- The Emergency Planning and Community Right-to-Know Act of 1986, which addressed the environmental and safety hazards posed by the storage and handling of toxic chemicals.

WELLNESS AND RESILIENCY

Workplaces must not only treat and prevent illness and injury but also promote health and well-being. Wellness, resiliency, and prevention of burnout have

TABLE 16-3 SELECT OCCUPATIONAL AND ENVIRONMENTAL HAZARDS

GROUP	HAZARD	EFFECT/SYMPTOMS	OCCUPATION/POTENTIAL SOURCE
Noxious Gases	Argon	Simple asphyxiant	Welder
	Ammonia	Pulmonary irritant, acute respiratory distress syndrome	Refrigeration; ammonia injection into soil as nitrogen-containing plant nutrient
	Carbon monoxide	Chemical asphyxiant	Mechanic, firefighter, blast furnace
	Helium	Simple asphyxiant	Electronics, aircraft manufacture
	Hydrogen cyanide	Chemical asphyxiant	Agricultural workers, plastics industry
	Hydrogen fluoride	Pulmonary irritant, ARDS	Glass etching
	Nitrogen	Simple asphyxiant, silo-fillers' disease	Welder, firefighter
Industrial Dusts Pneumonoconioses	Asbestos	Asbestosis, mesothelioma, lung cancer, pleural plaques, colon, renal and stomach cancer	Mining
	Coal	Emphysema, coal workers' pneumoconiosis	Coal mining, welders, diesel exhaust
	Silica	Silicosis	Sand blasting, granite countertop manufacture
Other Inorganic Dusts	Iron	Siderosis	Welding
	Tin	Stannosis	Tin
Vegetable Dusts	Cotton, flax, hemp	Byssinosis	Yarn and cotton manufacturer
	Flour dust	Occupational asthma	Baker
	Fungi in moldy hay	Farmer lung	Farming, agriculture
	Organic dusts or aerosols	Hypersensitivity pneumonitis	Mushroom farming, composting installations, vegetable storage
	Plicatic acid from western red cedar	Occupational asthma	Logging, house construction
	Sugar cane (fungus)	Bagassois	Sugar cane farming
Metals	Beryllium	Beryllium disease	Foundries, metal fabricators
	Cadmium	Pulmonary edema	Battery manufacturing, silver soldering
	Chromium	Lung cancer, nasal sinus cancer, sensitization	Welding on stainless steel, spray painting, operating chrome plating baths
	Cobalt	Asthma, allergic contact dermatitis, cardiomyopathy	Knee/hip replacement degradation
	Copper	Metal fume fever	Welding
	Lead	Lead toxicity, lethargy, wrist drop, lead line, anemia	Environmental lead, Ayurveda medication, battery production, glazes
	Magnesium	Metal fume fever	Welding, brazing
	Manganese	Parkinsonian syndrome	Welding, ore crushing, metallurgy
	Mercury—inorganic	Erethism, tremor, proteinuria	Amalgam workers, battery maker, fluorescent lamp maker
	Mercury—organic	Paresthesias, cognitive changes, cerebral palsy	Food chain: biomethylation of inorganic mercury by aquatic organisms
	Nickel	Sensitizer, dermatitis, asthma, nasal cancer	Welding alloys, stainless steel, plating
	Vanadium pentoxide	Pneumonitis, bronchitis, eye irritation	Cleaning fireboxes under boilers
	Zinc	Metal fume fever	Welding
Organic Compounds	Aliphatic hydrocarbon-n-hexane	Neuropathy, lipoid pneumonia	Solvent use, industrial cleaner and degreaser, mineral oil lubricants use
	Aromatic hydrocarbons—benzene	Aplastic anemia, leukemia	Shoe cements use, printing, fuel component
	Chlorinated hydrocarbons (e.g., trichloroethylene)	Headache, irritability, CNS depression, beverage/alcohol intolerance	Dry cleaning, chemical synthesis
	Chlorinated aromatics (e.g., dioxin)	Chloracne	Pulping and pesticide manufacturing
	Fluorinated hydrocarbons (e.g., perfluorochemicals)	Possibly carcinogen	Stain-resistant textiles and carpeting, water-repellent clothes, ski wax, Teflon manufacture
	Halogenated hydrocarbons (e.g., chloroform)	Nephrotoxicity, respiratory depression	Building, paper and board industries
Plastics	Acrylates/methacrylates	Irritant, contact allergen	Plexiglass manufacture, caulk use
	Fluoropolymers (e.g., Teflon)	Polymer fume fever	Teflon manufacture
	Vinyl chloride	Hepatic angiosarcoma	Vinyl chloride monomer, polymerization operations
Pesticides	Carbamates (e.g., carbaryl [Sevin])	Acetylcholine esterase inhibition	Pesticide manufacturing and application, forestry, pest management
	Fumigants (e.g., dibromochloropropane)	Oligospermia	Soil fumigant
	Fungicides (e.g., pentachlorophenol)	Aplastic anemia, chloracne	Wood preservative (telephone poles), dock, pier, and wharf structures
	Herbicides (e.g., paraquat)	Pulmonary fibrosis	Agriculture, forestry
	Organophosphates (e.g., parathion)	Acetylcholine esterase inhibition, paresthesias	Pesticide, agriculture, forestry
	Pyrethrins (e.g., permethrin)	Paresthesias with skin contact, dermatitis	Forestry, agriculture
Physical Hazards	Cold	Hypothermia, frostbite	Construction worker, outdoor trades
	Dysbarism	Fatigue, mottled skin, eardrum rupture	Commercial and sport divers
	Heat	Heat-related illness	Outdoor worker, athlete, farm worker
	Infrared radiation	Lens, cornea, retinal damage, skin burns	Glass blowing, smelting, foundry and forge operations
	Ionizing radiation	Cancer	Nuclear medicine, x-ray technician
	Lasers	Mild burns, cataracts	Welding, cosmetic surgery
	Noise	Hearing loss	Construction, mining, animal worker
	Radiofrequency radiation (radio waves and microwaves)	Burns	Telecommunications, electrosurgery
	Ultraviolet radiation	Photokeratoconjunctivitis or welders flash, cataracts	Plumbers, welders, machinery fitters, assemblers, toolmaker
	Vibration	Vibration white finger	Jackhammering, chainsawing

ARDS = acute respiratory distress syndrome; CNS = central nervous system.

become key issues throughout the workforce, and especially among health care workers, exacerbated by the COVID-19 pandemic.[16] For example, the provision of physical relaxation options can reduce stress among health care workers.[A1] Building collective and individual wellness and resiliency is a valuable skill to prevent burnout, which is an important occupational hazard that affects the personal and professional lives of employees and can have a substantial negative impact on patients, clients, and the financial well-being of institutions. The organization of work is a significant factor in causing and propagating burnout, and addressing such issues requires surveillance to identify the magnitude of the problem, careful consideration of key potential explanations, and a coordinated effort among front-line workers, mental health services, institutional leadership, and relevant stakeholders.[17,18]

EMERGENCY PREPAREDNESS AND DISASTER MANAGEMENT

The key roles for occupational and environmental medicine, as highlighted during the early months of the COVID-19 pandemic, include skills in emergency preparedness, emergency management, assessment of exposures, identification of hazards, disease prevention, surveillance, and population health. Knowledge of specific threats (including chemical, biologic, radiologic, and physical hazards) and bioterrorism agents (Chapter 19) can help protect employees, families, and the population at large. Emergency management planning includes resource mobilization, communication, procurement of medical products, financing, and contingency planning, often with the collaboration with local, state, or federal agencies. Addressing the mental health and safety needs of employees and responders is also critical.

ROLE OF THE INDIVIDUAL CLINICIAN

Clinicians must be agile to meet the challenges presented by the changing nature of work and our environment. They must recognize that care extends beyond merely attending to the clinical ailment in one worker to consider workplace risks that might affect other workers. Clinicians must consider both work-related and nonoccupational causes of illnesses, with the understanding, for example, that orthopedic or neurologic conditions may predispose to workplace injuries, and vice versa, that underlying lung disease may predispose to environmental pulmonary disease, and that preexisting anxiety or depression can exacerbate burnout. Referral to an occupational and environmental medicine specialist, who is trained in preventing, mitigating, and controlling hazards and managing workforces on a population level, is indicated when the degree of complexity rises above the scope of the general clinician.

17 EFFECTS OF CLIMATE CHANGE ON HEALTH

JEREMY HESS AND KRISTIE EBI

Climate is an important contextual element for human health and well-being. Anthropogenic climate change has demonstrated that long-held assumptions about the climate's stationarity are no longer valid, and our health systems and activities urgently need to be adjusted, in some cases fundamentally, to accommodate the ongoing shift in weather patterns. Health care education and practice must change, as well. To reduce harm, the health sector as a whole has an obligation to reduce its greenhouse gas emissions aggressively, and individual clinicians should acquire basic familiarity with the drivers and impacts of climate change, as well as priority strategies to reduce and manage risk.[1] Clinicians should understand how climate change will affect their patients and the communities in which they practice, and they should become proactive in improving the sustainability of health systems and services.

HOW CLIMATE CHANGE AFFECTS HEALTH

Climate, which is the multi-decade average of weather patterns in a given location, is the basis for long-term expectations, whereas weather is more variable and shapes day-to-day experiences. However, the implicit assumption that past climate is predictive of future weather patterns is no longer true. Anthropogenic climate change, driven by human emissions of greenhouse gases into the atmosphere, is undermining the assumption of stationarity.

Climate, which is a fundamental driver of health and disease,[2] determines the ecology of life in a particular place, including the social ecology of human settlement. Despite usual climatic variability, such as the recurring El Niño southern oscillation, the earth's climate has been quite stable within a relatively narrow range for millennia.[3]

Because of human emissions of greenhouse gases into the atmosphere, climatic expectations are no longer based on historical experience, with potentially profound implications for human health and, therefore, for public health and medical practice. Climate change affects health security, health determinants, risks for specific diseases, and how the health system's infrastructure and capacity will be able to respond to the challenges of the 21st century.

Anthropogenic climate change operates through simple physical principles. As a result of increased emissions of greenhouse gases (principally carbon dioxide but also methane, hydrofluorocarbons, and a host of other short-lived species), the earth's atmosphere is retaining a larger fraction of the sun's energy. This energy is transferred into land, water, and the atmosphere. For example, with more energy from warmer oceans, storms are stronger, contain more precipitation, and create more floods. Increased atmospheric heat dries out soils more quickly, and heat waves are stronger and persist for longer. Warming melts land-based ice and snow, thereby raising sea levels. Warming also speeds the photochemical reactions that are responsible for the formation of ground-level ozone, which is an air pollutant. Carbon dioxide levels in the oceans equilibrate with levels in the atmosphere, thereby increasing the concentration of carbonic acid; this weak acid dissolves calcium carbonate, thereby threatening collapse of marine ecosystems built on animals with shells. These impacts are already discernible with global average surface warming of 1.2° C above preindustrial temperatures. High-emission scenarios for the duration of the 21st century would result in 5.7° C of warming by the end of the century. Widespread, catastrophic impacts become increasingly likely with each additional unit of warming. For example, up to 90% of warm water corals are projected to die at 1.5° C of warming.

The implications for human health and well-being are significant. Health impacts result from a combination of underlying population-level vulnerability based on socio-demographics and health status, climate sensitivity of relevant disease pathways, and lack of investments in protective measures that could reduce exposure and promote prompt recovery in the event of expected adverse impacts.

The environmental impacts from climate change (Fig. 17-1) affect a wide range of pathways. Some pathways are relatively direct, such as heat exposure, which causes heat exhaustion and heat stroke (Chapter 95), as well as exacerbating stress on the cardiovascular, respiratory, and renal systems. Heat also affects determinants of health by reducing economic productivity and increasing the likelihood of violent crime. Extreme weather, including heat waves, storms, floods, wildfire, and climatic events such as droughts have significant health impacts by increasing injuries, exacerbations of chronic disease, anxiety, and depression.

Climate change also affects a wide range of other, less direct pathways that are important to human health, from air pollution (heat and sunlight affect the development of ground-level ozone and wildfires release particulate air pollution) to aeroallergens (the onset and intensity of pollen season are correlated with temperature).[4] Infectious diseases are particularly sensitive to climatic shifts as a result of changes in the reproductive rates and geographic distribution of pathogens (Chapter 303) including vectors that can transmit waterborne and foodborne diseases, such as the tick that can carry Lyme

17 EFFECTS OF CLIMATE CHANGE ON HEALTH

JEREMY HESS AND KRISTIE EBI

Climate is an important contextual element for human health and well-being. Anthropogenic climate change has demonstrated that long-held assumptions about the climate's stationarity are no longer valid, and our health systems and activities urgently need to be adjusted, in some cases fundamentally, to accommodate the ongoing shift in weather patterns. Health care education and practice must change, as well. To reduce harm, the health sector as a whole has an obligation to reduce its greenhouse gas emissions aggressively, and individual clinicians should acquire basic familiarity with the drivers and impacts of climate change, as well as priority strategies to reduce and manage risk.[1] Clinicians should understand how climate change will affect their patients and the communities in which they practice, and they should become proactive in improving the sustainability of health systems and services.

HOW CLIMATE CHANGE AFFECTS HEALTH

Climate, which is the multi-decade average of weather patterns in a given location, is the basis for long-term expectations, whereas weather is more variable and shapes day-to-day experiences. However, the implicit assumption that past climate is predictive of future weather patterns is no longer true. Anthropogenic climate change, driven by human emissions of greenhouse gases into the atmosphere, is undermining the assumption of stationarity.

Climate, which is a fundamental driver of health and disease,[2] determines the ecology of life in a particular place, including the social ecology of human settlement. Despite usual climatic variability, such as the recurring El Niño southern oscillation, the earth's climate has been quite stable within a relatively narrow range for millennia.[3]

Because of human emissions of greenhouse gases into the atmosphere, climatic expectations are no longer based on historical experience, with potentially profound implications for human health and, therefore, for public health and medical practice. Climate change affects health security, health determinants, risks for specific diseases, and how the health system's infrastructure and capacity will be able to respond to the challenges of the 21st century.

Anthropogenic climate change operates through simple physical principles. As a result of increased emissions of greenhouse gases (principally carbon dioxide but also methane, hydrofluorocarbons, and a host of other short-lived species), the earth's atmosphere is retaining a larger fraction of the sun's energy. This energy is transferred into land, water, and the atmosphere. For example, with more energy from warmer oceans, storms are stronger, contain more precipitation, and create more floods. Increased atmospheric heat dries out soils more quickly, and heat waves are stronger and persist for longer. Warming melts land-based ice and snow, thereby raising sea levels. Warming also speeds the photochemical reactions that are responsible for the formation of ground-level ozone, which is an air pollutant. Carbon dioxide levels in the oceans equilibrate with levels in the atmosphere, thereby increasing the concentration of carbonic acid; this weak acid dissolves calcium carbonate, thereby threatening collapse of marine ecosystems built on animals with shells. These impacts are already discernible with global average surface warming of 1.2° C above preindustrial temperatures. High-emission scenarios for the duration of the 21st century would result in 5.7° C of warming by the end of the century. Widespread, catastrophic impacts become increasingly likely with each additional unit of warming. For example, up to 90% of warm water corals are projected to die at 1.5° C of warming.

The implications for human health and well-being are significant. Health impacts result from a combination of underlying population-level vulnerability based on socio-demographics and health status, climate sensitivity of relevant disease pathways, and lack of investments in protective measures that could reduce exposure and promote prompt recovery in the event of expected adverse impacts.

The environmental impacts from climate change (Fig. 17-1) affect a wide range of pathways. Some pathways are relatively direct, such as heat exposure, which causes heat exhaustion and heat stroke (Chapter 95), as well as exacerbating stress on the cardiovascular, respiratory, and renal systems. Heat also affects determinants of health by reducing economic productivity and increasing the likelihood of violent crime. Extreme weather, including heat waves, storms, floods, wildfire, and climatic events such as droughts have significant health impacts by increasing injuries, exacerbations of chronic disease, anxiety, and depression.

Climate change also affects a wide range of other, less direct pathways that are important to human health, from air pollution (heat and sunlight affect the development of ground-level ozone and wildfires release particulate air pollution) to aeroallergens (the onset and intensity of pollen season are correlated with temperature).[4] Infectious diseases are particularly sensitive to climatic shifts as a result of changes in the reproductive rates and geographic distribution of pathogens (Chapter 303) including vectors that can transmit waterborne and foodborne diseases, such as the tick that can carry Lyme

ABSTRACT

Climate is an important contextual element for human health and well-being. Anthropogenic climate change has demonstrated that long-held assumptions about the climate's stationarity are no longer valid, and our health systems and activities urgently need to be adjusted, in some cases fundamentally, to accommodate the ongoing shift in weather patterns. Health care education and practice must change, as well. To reduce harm, the health sector as a whole has an obligation to reduce its greenhouse gas emissions aggressively, and individual clinicians should acquire basic familiarity with the drivers and impacts of climate change, as well as priority strategies to reduce and manage risk. Clinicians should understand how climate change will affect their patients and the communities in which they practice, and they should become proactive in improving the sustainability of health systems and services.

disease (Chapter 296) and the mosquitoes that can carry dengue fever, Zika virus, chikungunya, and yellow fever (Chapters 351 and 352), and skin and soft tissue infections.[5] Nutritional impacts derive from several different pathways, including disruption of food production from extreme weather, decreased protein and micronutrient content of staple crops, and collapse of productive ecosystems that are key for subsistence.[6] On a macro level, rising sea levels and ecologic stressors are expected to lead to widespread and challenging migration and displacement.

RECENT EVIDENCE AND PROJECTED IMPACTS OF CLIMATE CHANGE ON HEALTH

Health impacts of climate change are already apparent. Patterns of emergence include sentinel events and outbreaks (Table 17-1), shifts in endemicity, introduction and establishment of new diseases, and changing patterns of underlying risks and stressors that affect determinants of health. For instance, heat-related mortality rates are increasing globally, and 37% of heat-related mortality can now be attributed to climate change.[7]

An outbreak of *Vibrio parahaemolyticus* (Chapter 278) in Alaska in 2004 shifted the range of that pathogen over 1000 km to the north; Lyme disease (Chapter 296) is moving steadily northward on the North American continent[8]; ragweed allergy (Chapter 230), historically rare in Europe, is becoming increasingly prevalent[9]; and rising sea levels are requiring relocation from a wide range of coastal communities (see Fig. 17-1).[10] Other shifts, such as changes in the range of *Aedes albopictus,* which transmits Zika, dengue, and chikungunya (Chapters 351 and 352), and *Phlebotomus,* which transmits leishmaniasis (Chapter 319), are driven by climate change and increase risk of these infectious diseases.[11]

The timing and magnitude of the most severe impacts will depend on multiple choices made at the societal level in coming decades. Substantial future warming is inevitable based on greenhouse gas emissions to date. Through roughly mid-century, choices regarding health and social protections, including the degree to which societies invest in basic physical and mental health care, health systems, education, economic protection, and climate-resilient infrastructure, will be the primary determinant of climate impacts. The extent to which climatic hazards and associated stresses could cause severe impacts after mid-century, overwhelming protections in many locations, is a function of preparedness and of how successfully the world is able to reduce greenhouse gas emissions in the next two decades.

HEALTH CARE PROFESSIONALS AND CLIMATE CHANGE

Clinicians should have a basic understanding of what constitutes a climate-resilient health system and how climate change may affect the populations for which they care. Practitioners should advocate for reducing the health sector's substantial greenhouse gas emissions and participate in building climate-resilient health systems (E-Fig. 17-1).

Although this framework is primarily designed for public health officials and leaders of health systems, it has clear relevance to clinicians across the health sector. An emphasis on leadership, for example, highlights the need for clinicians to speak publicly about preparing for climate change and its impacts so as to prioritize planning and public-facing policies, measures, and engagements.[12] The emphasis on ensuring climate-smart risk monitoring and early warning encompasses a wide range of activities, from surveillance of indicators of climate change (e.g., extreme heat events and heat-related illness; pollen season parameters and allergic respiratory disease) to an understanding of how shifts in climate may affect individual and community health. Other important aspects of adapting to climate change in the health sector include engagement in disaster planning and preparedness exercises (in anticipation of more frequent and severe extreme heat events, storms, wildfires, and power failures), as well as the development and implementation of early warning systems[13] for extreme events, and promoting disaster risk reduction to prevent and limit adverse health impacts from disasters.

Reducing greenhouse gas emissions from the health sector is also an important priority.[14] The health sector's emission of greenhouse gases constitutes approximately 4% of the global total,[15] larger than global emissions from air travel. In the United States, the percentage is even higher—the health sector is responsible for nearly 10% of emissions.[16] These emissions are clearly associated with health harms from co-emitted air pollution. In the United States, for example, air pollution from health care causes the loss of nearly 400,000 disability-adjusted years of life[17] and approximately 4.2 million premature deaths globally each year. The harms from air pollution associated with the health care sector in the United States are of the same order of magnitude as harms associated with medical errors.

RESEARCH PRIORITIES FOR CLIMATE CHANGE AND HEALTH

The health sector also must develop additional evidence to support the practice innovations that will be needed to respond to the challenges that climate change presents.[18,19] Areas of emphasis include understanding how climate change harms health; how to diagnose these harms in individuals and across populations; how to devise, implement, and evaluate interventions to reduce these harms; and how to make more accurate prognostic estimates about how current trends and potential interventions could affect the future.

TABLE 17-1 EXAMPLES OF CLIMATE-RELATED HAZARDS, UNDERLYING VULNERABILITIES, AND INFECTIOUS DISEASE OUTCOME

HAZARD	VULNERABILITY	INFECTIOUS DISEASE OUTBREAKS
U.S. hurricane Katrina	Lack of water, sanitation, and hygiene in large shelters for evacuees	Norovirus gastroenteritis
Mozambique cyclones Idai and Kenneth	Lack of water, sanitation, and hygiene and overcrowding in camps for displaced	Diarrheal diseases, malaria
128 flooding, storm, and drought events	Displacement	Measles, cholera, cutaneous leishmaniasis, dengue
Yemen heavy rainfall and elevated temperature	Contamination of surface water	Cholera
Pakistan monsoon flooding	Record-breaking floods	Acute diarrhea, leptospirosis, malaria, leishmaniasis
European heavy rain	Overwhelmed water treatment and distribution systems	Waterborne diseases, such as cryptosporidium
African drought	Water scarcity and hygiene	Cholera

18 RADIATION INJURY

DAVID J. BRENNER

IONIZING RADIATION

DEFINITIONS

The ionizing radiations are x- and gamma rays, alpha and beta particles, and (indirectly) neutrons. Unlike non-ionizing radiations such as radio waves, microwaves, infrared light, visible light, and ultraviolet (UV) radiation, ionizing radiations have enough energy to knock electrons out of atomic or molecular orbits, thereby potentially breaking chemical bonds in key biomolecules such as DNA.

A key difference among the various ionizing radiations is their ability to penetrate matter (Fig. 18-1). For example, alpha particles have very limited range, measured in micrometers. Because alpha particles cannot penetrate skin, their health significance is entirely in the context of internal exposure by inhalation or ingestion of alpha-emitting radioactive materials. Beta particles, which have intermediate ranges, can typically be stopped by a piece of paper. By contrast, x-rays, gamma rays, and neutrons are highly penetrating and are hard to shield.

Ionizing radiations are emitted by radioactive materials, which can either be naturally occurring or can be man-made, using machines such as nuclear reactors. The amount of ionizing radiation emitted by a radioactive material is determined by its activity, measured in becquerels (1 Bq = 1 radioactive disintegration/second) or Curies (Ci).

Radioactivity should be distinguished from absorbed dose, which is a measure of how much ionizing energy is actually absorbed by a structure of interest, such as a person or an organ. The basic measurement unit of absorbed dose, which is the energy deposited per unit mass, is the Gray (1 Gy = 1 J/kg). *Equivalent dose* takes into account the fact that not all types of radiation are equally effective, *effective dose* takes into account the fact that not all organs in the body are equally sensitive to ionizing radiation, and *collective dose* is a measure of the effective dose delivered summed over a whole exposed population (Table 18-1).

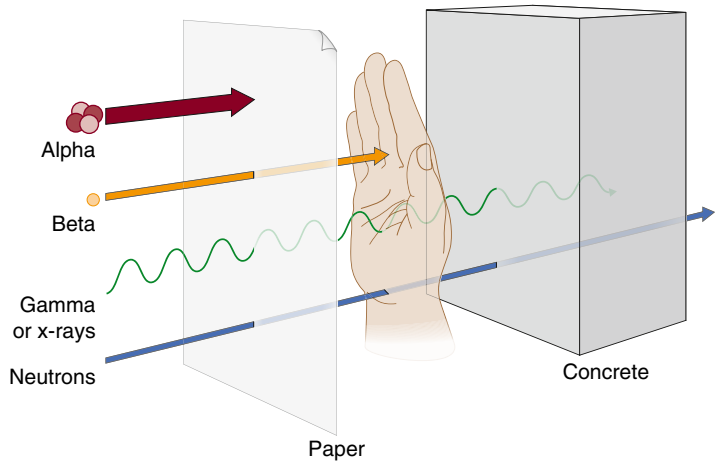

FIGURE 18-1. Schematic illustration of the relative ranges of alpha particles, beta rays, x- or gamma rays, and neutrons as they penetrate through matter.

HEALTH CARE PROFESSIONALS AND CLIMATE CHANGE

Clinicians should have a basic understanding of what constitutes a climate-resilient health system and how climate change may affect the populations for which they care. Practitioners should advocate for reducing the health sector's substantial greenhouse gas emissions and participate in building climate-resilient health systems (E-Fig. 17-1).

Although this framework is primarily designed for public health officials and leaders of health systems, it has clear relevance to clinicians across the health sector. An emphasis on leadership, for example, highlights the need for clinicians to speak publicly about preparing for climate change and its impacts so as to prioritize planning and public-facing policies, measures, and engagements.[12] The emphasis on ensuring climate-smart risk monitoring and early warning encompasses a wide range of activities, from surveillance of indicators of climate change (e.g., extreme heat events and heat-related illness; pollen season parameters and allergic respiratory disease) to an understanding of how shifts in climate may affect individual and community health. Other important aspects of adapting to climate change in the health sector include engagement in disaster planning and preparedness exercises (in anticipation of more frequent and severe extreme heat events, storms, wildfires, and power failures), as well as the development and implementation of early warning systems[13] for extreme events, and promoting disaster risk reduction to prevent and limit adverse health impacts from disasters.

Reducing greenhouse gas emissions from the health sector is also an important priority.[14] The health sector's emission of greenhouse gases constitutes approximately 4% of the global total,[15] larger than global emissions from air travel. In the United States, the percentage is even higher—the health sector is responsible for nearly 10% of emissions.[16] These emissions are clearly associated with health harms from co-emitted air pollution. In the United States, for example, air pollution from health care causes the loss of nearly 400,000 disability-adjusted years of life[17] and approximately 4.2 million premature deaths globally each year. The harms from air pollution associated with the health care sector in the United States are of the same order of magnitude as harms associated with medical errors.

RESEARCH PRIORITIES FOR CLIMATE CHANGE AND HEALTH

The health sector also must develop additional evidence to support the practice innovations that will be needed to respond to the challenges that climate change presents.[18,19] Areas of emphasis include understanding how climate change harms health; how to diagnose these harms in individuals and across populations; how to devise, implement, and evaluate interventions to reduce these harms; and how to make more accurate prognostic estimates about how current trends and potential interventions could affect the future.

TABLE 17-1 EXAMPLES OF CLIMATE-RELATED HAZARDS, UNDERLYING VULNERABILITIES, AND INFECTIOUS DISEASE OUTCOME

HAZARD	VULNERABILITY	INFECTIOUS DISEASE OUTBREAKS
U.S. hurricane Katrina	Lack of water, sanitation, and hygiene in large shelters for evacuees	Norovirus gastroenteritis
Mozambique cyclones Idai and Kenneth	Lack of water, sanitation, and hygiene and overcrowding in camps for displaced	Diarrheal diseases, malaria
128 flooding, storm, and drought events	Displacement	Measles, cholera, cutaneous leishmaniasis, dengue
Yemen heavy rainfall and elevated temperature	Contamination of surface water	Cholera
Pakistan monsoon flooding	Record-breaking floods	Acute diarrhea, leptospirosis, malaria, leishmaniasis
European heavy rain	Overwhelmed water treatment and distribution systems	Waterborne diseases, such as cryptosporidium
African drought	Water scarcity and hygiene	Cholera

18 RADIATION INJURY

DAVID J. BRENNER

IONIZING RADIATION

DEFINITIONS

The ionizing radiations are x- and gamma rays, alpha and beta particles, and (indirectly) neutrons. Unlike non-ionizing radiations such as radio waves, microwaves, infrared light, visible light, and ultraviolet (UV) radiation, ionizing radiations have enough energy to knock electrons out of atomic or molecular orbits, thereby potentially breaking chemical bonds in key biomolecules such as DNA.

A key difference among the various ionizing radiations is their ability to penetrate matter (Fig. 18-1). For example, alpha particles have very limited range, measured in micrometers. Because alpha particles cannot penetrate skin, their health significance is entirely in the context of internal exposure by inhalation or ingestion of alpha-emitting radioactive materials. Beta particles, which have intermediate ranges, can typically be stopped by a piece of paper. By contrast, x-rays, gamma rays, and neutrons are highly penetrating and are hard to shield.

Ionizing radiations are emitted by radioactive materials, which can either be naturally occurring or can be man-made, using machines such as nuclear reactors. The amount of ionizing radiation emitted by a radioactive material is determined by its activity, measured in becquerels (1 Bq = 1 radioactive disintegration/second) or Curies (Ci).

Radioactivity should be distinguished from absorbed dose, which is a measure of how much ionizing energy is actually absorbed by a structure of interest, such as a person or an organ. The basic measurement unit of absorbed dose, which is the energy deposited per unit mass, is the Gray (1 Gy = 1 J/kg). *Equivalent dose* takes into account the fact that not all types of radiation are equally effective, *effective dose* takes into account the fact that not all organs in the body are equally sensitive to ionizing radiation, and *collective dose* is a measure of the effective dose delivered summed over a whole exposed population (Table 18-1).

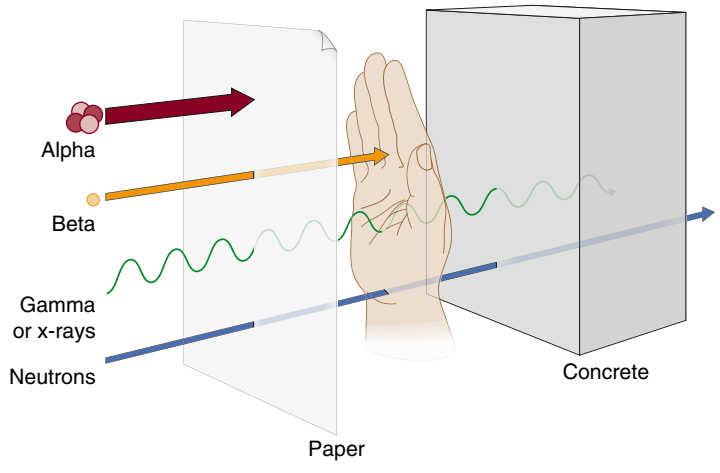

FIGURE 18-1. Schematic illustration of the relative ranges of alpha particles, beta rays, x- or gamma rays, and neutrons as they penetrate through matter.

ABSTRACT

Both ionizing and non-ionizing radiations can cause radiobiologic damage to a variety of tissues. Some of these damages can be mitigated by preventive measures. Radiation can also be used therapeutically as a disinfectant.

TABLE 18-1 STANDARD QUANTITIES AND UNITS ASSOCIATED WITH EXPOSURE TO IONIZING RADIATION

QUANTITY	DEFINITION	UNITS
Absorbed dose	Energy per unit mass	Gray (Gy)
Equivalent dose	Average dose × radiation-type-specific radiation weighting factor	Sievert (Sv)
Effective dose	Sum of equivalent doses to all exposed organs, each multiplied by an appropriate organ-relative sensitivity factor	Sievert (Sv)
Collective dose	Sum of effective doses to a population of exposed individuals	Person-Sv

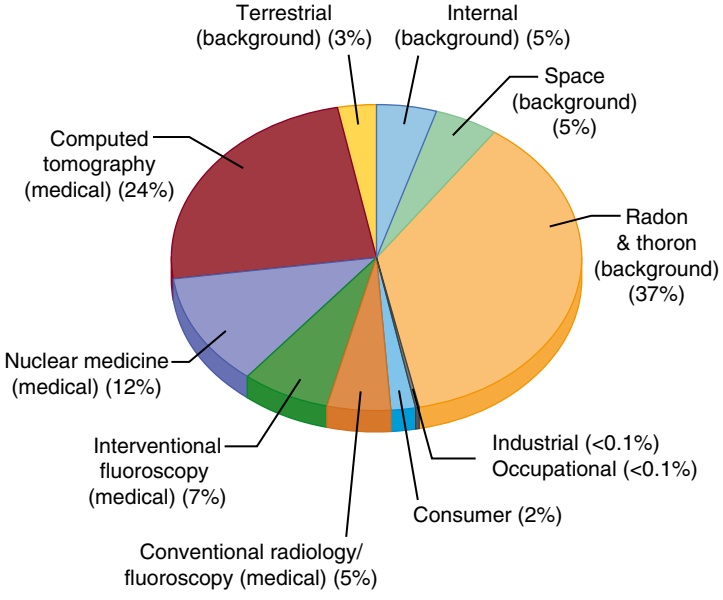

FIGURE 18-2. The major sources of radiation exposure to an average individual in the United States. (From Hall EJ, Giaccia AJ. *Radiobiology for the Radiologist*. 7th ed. Philadelphia: Lippincott Williams & Wilkins; 2012.)

EPIDEMIOLOGY

Radiation exposure can come from natural sources, therapeutic or diagnostic medical exposures, or accidental exposures to individuals or to large populations. Natural sources and radiologic examinations are the major (and about equal) contributors to the overall collective radiation dose to the U.S. population (Fig. 18-2).

Natural Sources of Ionizing Radiation

The largest naturally occurring source of radiation is from radon gas, which is an alpha-particle emitter. Radon is a constituent component of all rocks, particularly granite-type rocks. Radon is a member of a chain of radioactive elements that starts with naturally occurring uranium and radioactively decays from one element to the next; uniquely in this chain of elements, radon is a gas, which can emerge from the ground and result in high levels in the basement and higher floors of houses. Long-term exposure to radon gas can cause lung cancer because emitted alpha particles in the lung can damage cells in the bronchial epithelium. The three other main sources of naturally occurring radiation exposure are from terrestrial exposure (gamma rays emitted from naturally occurring radioactive materials in the ground), from space radiations (mainly intergalactic cosmic rays that penetrate through the atmosphere), and internal radiation (from naturally occurring radioactive elements in the body, such as potassium-40).

Medical Exposures

The single largest source of medical exposure is computed tomography (CT), which on average contributes about 25% of the collective dose to the U.S. population. This source of exposure is recent because CT has been commonly used only since the 1980s. Now, however, about 70 million CT scans are performed annually in the United States. In addition to CT, nuclear medicine, interventional fluoroscopy, and conventional radiography together constitute about 25% of the overall collective dose to the U.S. population.

TABLE 18-2 ESTIMATED RELEASES OF RADIOACTIVE IODINE AND RADIOACTIVE CESIUM FROM THE FOUR HISTORICALLY BIGGEST NUCLEAR POWER PLANT ACCIDENTS

	^{131}I (TBq)	$^{137/134}$Cs (TBq)
Windscale, 1957	750	20
Three Mile Island, 1979	1	0.000001
Chernobyl, 1986	1,800,000	110,000
Fukushima, 2011	~500,000	~20,000

Radiologic Accidents

Since the widespread introduction of nuclear power plants, major radiologic accidents have become an intermittent, although rare, source of radiation exposure. The accidents at Chernobyl in 1986 and at Fukushima in 2011 released far more radioactivity than any other accidents (Table 18-2). For those individuals exposed to low radiation doses, many common symptoms reported in the immediate aftermath were not necessarily physical health problems directly attributable to radiation exposure but rather psychological and psycho-social effects.[1]

Radiologic Terrorism

In the broadest of terms, two different types of such threats exist, one from an improvised nuclear device and the other from a radiologic dispersal device, sometimes called a *dirty bomb*.[2,3] The two are very different in terms of their potential consequences and also their likelihood of occurrence.

The consequences of exploding an improvised nuclear device, perhaps similar to those detonated at Hiroshima or Nagasaki, although more likely exploded at ground level, would be devastating in terms of loss of life and major injuries. For example, a 20-kT daytime surface improvised nuclear device explosion in midtown Manhattan might involve 2.2 million people exposed to high radiation doses, of whom perhaps only 1.6 million might survive.

By contrast, the consequences of exploding a radiologic dispersal device or dirty bomb, dispersing what could be very small or very large amounts of radioactive material, would likely involve a relatively small spatial area in which individuals are significantly exposed, as well as a much larger area in which individuals are exposed to very low levels of radioactivity. The significance of a dirty bomb depends on the amount of radioactivity in the device and the efficiency with which the explosion aerosolizes and disperses the radioactive material. Of course, the consequences of a radiologic dispersal device extend beyond health effects and could potentially involve large-scale social and economic disruption.

PATHOBIOLOGY

Ionizing radiation can both mutate cells and cause cell death. The key initial damage site is a DNA double-strand break, although other types of damage are possible. This double-strand break is generally repaired by a variety of mechanisms, the most important of which for ionizing radiation damage is nonhomologous end rejoining. Imprecise nonhomologous end rejoining can lead to small mutations, whereas double-strand break misrepair (i.e., the wrong ends of breaks being rejoined to each other) can lead to chromosomal translocations, inversions, telomere fusions, and other large-scale chromosomal structural alterations.

Although chromosomal translocations, inversions, and point mutations are typically nonlethal lesions, such radiation-induced chromosomal aberrations can be the initial lesions associated with carcinogenesis. For example, the initial event in many hematopoietic cancers (Chapters 168 and 170) is often a recurrent translocation, which in turn results in the fusion of genes located at the translocation breakpoints. Radiation-induced point mutations and deletions also are often associated with loss of heterozygosity in tumor suppressor genes.

Misrepair of double-strand breaks can also result in dicentric chromosome aberrations and centric rings (Chapter 166), which are generally lethal lesions that cause reproductive cell death in which a cell loses its ability to divide. A second, quite different mechanism of radiation-induced cell death is apoptosis, or programmed cell death, that, for example, is important after radiation exposure of hematopoietic cells and jejunal crypt cells.

CLINICAL MANIFESTATIONS

The consequences of radiation exposure are dose dependent and are also dependent on whether the exposure is to the whole body or only part of the body. After high doses of whole-body exposure, the major consequences are acute radiation syndromes, which may be fatal. After high doses of partial-body exposure, such as after radiotherapy, the consequences are highly organ specific. These high-dose tissue reactions are deterministic, meaning that there typically is a threshold below which the effects are not seen, with the severity of the effect increasing with increasing dose. By contrast, the major concern at lower doses is with stochastic effects, in which there is no dose threshold, and it is the probability of the effect that increases with increasing dose. The most important example here is radiation-induced cancer.

Acute Radiation Syndromes

The radiation dose needed to mitotically kill active dividing cells is far less than the dose needed to remove the functioning ability of differentiated cells. As a result, acute radiation syndromes generally relate to the failure of precursor cells to provide replacements for functional cells within an organ, when the latter need replacement. Acute radiation syndromes typically progress through four stages: prodromal, clinical latency, manifest illness, and recovery or death.

Prodromal Stage

Prodromal (early) symptoms occur shortly after irradiation, with the radiation dose determining the severity, duration, and onset. Typical prodromal symptoms include nausea, vomiting, anorexia, fatigue, diarrhea, abdominal cramping, and dehydration. At very high doses, these symptoms can appear within a few minutes of exposure; but at somewhat lower doses, they may not appear for many hours, if at all.

Latency Period

After the prodromal stage, a latency period typically precedes manifest illness. This delay occurs because the subsequent syndromes (hematopoietic or gastrointestinal) involve the failure of relevant tissues to self-renew, and manifest illness does not occur until after the typical cellular turnover times in these tissues.

Manifest Illness

The *hematopoietic syndrome* results from whole-body or significant partial-body exposure to 3 to 9 Gy. At these doses, radiation kills mitotically active hematopoietic precursor cells. Symptoms then result from lack of circulating blood elements some 4 to 8 weeks later as circulating cells die and are not replaced. The hematopoietic syndrome may manifest as infections and possible hemorrhage, impairment of immune mechanisms, and potentially multiple-organ failure.

The *gastrointestinal syndrome* usually occurs after whole-body or significant partial-body exposure of about 8 Gy and above. These doses lead to death of intestinal stem cells in the regenerating crypts. Symptoms then result when differentiated cells of the villi are naturally sloughed off, but stem cells are unable to produce new cells, thereby leading to depopulation of the epithelial lining of the gastrointestinal tract. After a latency period of about 7 days, loss or significant shortening of the villi on the intestinal epithelium leads to bacterial growth and increased risk for sepsis. Common symptoms include anorexia, nausea, vomiting, prolonged bloody diarrhea, abdominal cramps, dehydration, and weight loss. Should death occur, it is typically 7 to 10 days later.

At extremely high radiation doses, death is typically from the *cerebrovascular syndrome* within a few days after exposure. The cause of death is believed to be because changes in permeability of small blood vessels in the brain lead to cerebral edema.

Organ-Specific Late Effects after Radiotherapy

Iatrogenic organ-specific late effects follow quite predictably after targeted radiation therapy in which the organ in question is irradiated, although the severity of the response is less predictable.[4] These tissue effects can be divided into global organ responses and focal responses, in which a particular part of the organ is differentially irradiated (Table 18-3).

As one example, significant radiation exposure to the heart increases the risk for subsequent major heart disease.[5,6] These risks have been most notable in women who have had radiotherapy for left-sided breast cancer (Chapter 183), patients treated with mantle radiation for Hodgkin lymphoma (Chapter 172), and some patients treated for lung tumors adjacent to the heart. Radiation effects to the heart can be wide ranging, including to the coronary arteries, the myocardium, the heart valves, and the pericardial sac. The increased risk, which is proportional to the cardiac dose, begins a few years after exposure and continues throughout life. These radiation risks appear to be multiplicative of the natural background cardiac risks, so patients with preexisting cardiac risk factors are likely to have greater absolute increases in their risk for radiation-induced cardiac disease. Radiation damage to the lungs (Chapter 82)[7] and colorectal area (Chapter 128)[8] also can cause significant morbidity.

TABLE 18-3 TYPICAL ORGAN-SPECIFIC DETERMINISTIC LATE EFFECTS AFTER HIGH-DOSE RADIOTHERAPY

ORGAN	LOCAL END POINT	GLOBAL END POINT
Brain, cranial nerves	Focal weakness, vision loss	Neurocognitive deficit
Lung	Bronchial stricture	Shortness of breath
Heart	Coronary stenosis	Pericarditis, cardiomyopathy
Bladder	Bleeding	Urinary frequency, diarrhea
Bowel	Ischemia, bleeding	Enteritis

Adapted with changes from Rubin P, Constine LS, Marks LB, eds. *ALERT—Adverse Late Effects of Cancer Treatment*. Vol. 1: General Concepts and Specific Precepts. Heidelberg: Springer; 2014.

Stochastic Effects of Radiation

In contrast to the deterministic organ-based effects of radiation, ionizing radiation also produces stochastic effects, whereby the severity of the disease is not dose dependent, but the probability of an effect increases with increasing dose. These effects are largely due to radiation-induced mutations of target cells, as opposed to cell killing, with by far the most important effect being radiation carcinogenesis. Other potential radiation-induced stochastic health effects include deleterious radiation-induced genetic effects to subsequent generations.

Radiation Carcinogenesis

In general, radiation acts as a multiplier of natural background cancer rates, although there are exceptions, such as radiation-induced breast cancer, in which the radiation risks are largely independent of the natural background rates, and prostate cancer, which generally is not a radiogenic tumor. Most radiation-induced cancers occur many years after radiation exposure, typically in the same "cancer-prone" years (about 55 to 75 years of age), as do naturally occurring cancers. Exceptions include radiation-induced hematopoietic cancers and radiation-induced thyroid cancers, both of which typically occur within a few years of radiation exposure. Sensitivity to radiation-induced cancer is age dependent, with people exposed at younger ages having higher lifetime cancer risks.

Most of what is known quantitatively about the radiation-induced risks for cancer comes from studies of atomic bomb survivors, who had measurable increased subsequent risks for cancer: at a 1 Gy dose at follow-up more than 50 years later, atomic bomb survivors showed a 64% increased risk of solid cancer in females and a 20% increase in males. Despite much study, hereditary effects in the children of atomic bomb survivors was not detected.

Long-term survivors of radiation therapy also have a small but significantly increased risk of radiation-associated second cancers.[9] At low radiation doses, for example, below 0.1 Gy, epidemiologic studies are difficult to perform and interpret because of the difficulty in quantifying a small excess cancer risk above the natural human lifetime cancer risk of about 40%. However large-scale epidemiologic studies in children who have received CT scans or had small radioactive iodine exposures at Chernobyl showed an increased risk of radiation-induced cancer.

Radiation Cataractogenesis

Ionizing radiation induces ocular cataracts (Chapter 391) with a probability, severity, and latency related to the radiation dose.[10] Studies of atomic bomb survivors, Chernobyl cleanup workers, astronauts, and radiologic technicians have all shown increased incidence of cataracts, even at radiation doses below 1 Gy. Radiation cataractogenesis is a result of radiation damage to dividing cells in the lens. Because there are essentially no mechanisms in the lens for removal of damaged cells, the resulting nontranslucent lens fibers migrate toward the posterior pole of the lens, where they represent the first stage of a cataract. Posterior subcapsular cataracts are less common than nuclear or cortical cataracts in the general population but are the type most commonly associated with ionizing radiation.

DIAGNOSIS

The diagnosis of radiation injury can be considered in two different contexts. The first context is when the radiation dose is not known, and the goal is to estimate the dose that was delivered in order to optimize treatment. Examples

include accidents and radiologic terrorism scenarios. The second context is when the radiation dose is known, in particular after radiotherapy. Here the sequelae (see Table 18-3) are predictable, but the timing and the severity of the injury are less predictable.

Radiation Biodosimetry

For an individual exposed to a large whole-body radiation dose, the first critical task is to estimate the radiation dose that the individual received, because different syndromes (hematopoietic, gastrointestinal, cerebrovascular) are associated with different radiation dose ranges. The technique for estimating exposures to individuals is known as *radiation biodosimetry*. In this diagnostic process, a small amount of a body tissue, such as blood or urine, is analyzed, and dose-dependent end points in the sample are measured to provide an estimated dose. The most common end point of DNA damage, such as micronuclei, in blood samples, can now be assessed by commonly available high-throughput technologies. Other practical endpoints include gene expression in blood or induction of metabolites in urine.

Post-Radiotherapy Sequelae

Deterministic radiation-induced organ syndromes are seen at reasonably predictable intervals after radiation therapy. For example, radiation pericarditis (Chapter 62) can develop during treatment or months to years later, initially with an effusion and progressing to pericardial constriction. Radiation enterocolitis (Chapter 126) can develop 6 to 12 months after radiation doses of 40 to 60 Gy for prostate cancer or gynecologic malignancies. Radiation-induced pulmonary injury can be detected in up to 50% of patients who receive thoracic radiation therapy, but only a minority of them will develop clinical symptoms (Chapter 82). In addition, the majority of all radiotherapy patients experience acute skin or mucosal toxicity, in particular radiation dermatitis, oral mucositis, and xerostomia.

TREATMENT

Whole-Body Exposure Syndromes

For exposures below 2 Gy, no immediate treatment is needed (Fig. 18-3). For patients with potential hematopoietic syndrome (doses between 2 and 10 Gy), the two primary treatment approaches are: first, antibiotics and barrier nursing, which can raise the human LD_{50} (the dose at which 50% of exposed individuals die) from about 4 Gy to 8 Gy; and second, granulocyte colony-stimulating factor (G-CSF).[11] Subcutaneous G-CSF, filgrastim (10 μg/kg daily for up to 2 weeks), or pegfilgrastim (two 6-mg doses one week apart) are approved by the U.S. Food and Drug Administration (FDA) for the treatment of patients with radiation-induced myelosuppression following a radiologic/nuclear incident. A placenta-derived adherent stromal cell has been approved by the FDA for emergency treatment of acute radiation exposure in a possible nuclear event.[12]

The role of bone marrow transplantation in treating individuals with the hematopoietic syndrome is probably quite limited at doses less than about 9 Gy. In the aftermath of the Chernobyl accident, for example, 13 individuals underwent bone marrow transplantation, and three deaths were directly attributed to the sequelae of the procedure in patients in whom the transplantation was not indicated based on their exposure. Conservative treatment regimens, including antibiotics, cytokine therapy, transfusions, and nursing, are clearly effective, but current treatment options are very limited at doses above about 10 Gy, when the gastrointestinal syndrome becomes the dominant cause of death.

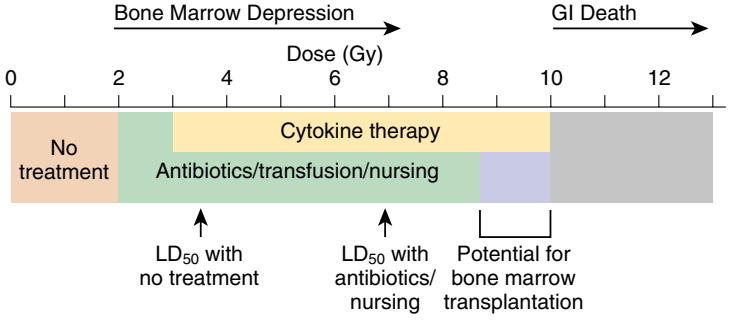

FIGURE 18-3. Schematic recommended treatment for acute radiation syndromes, as a function of the estimated dose that the individual received. Note the very narrow dose window for which bone marrow transplantations are potentially useful. GI = gastrointestinal; Gy = Gray units; LD_{50} = dose of radiation expected to kill 50% of exposed cells within 30 days. (Adapted with changes from Hall EJ. *Radiobiology for the Radiologist*. 7th ed. Philadelphia: Lippincott Williams & Wilkins; 2012.)

Radiotherapy Sequelae

Proton beam therapy may have the potential to reduce side effects compared with other modern versions of radiation therapy.[A1] However, these benefits appear to be limited to specific situations, especially locally advanced esophageal cancer and pediatric brain tumors,[13] and the cost-benefit ratio of proton beam therapy is uncertain. Comparatively few drugs have been approved by the FDA for minimizing radiotherapy-associated sequelae. Amifostine (200 mg/m^2 given intravenously daily before each fraction of radiation therapy)[14] is FDA-approved for minimizing radiotherapy-associated xerostomia, but its use has been limited by significant toxicity, and data on its efficacy are conflicting.[15] Several drugs have been designed to mitigate or treat the damage caused by radiation therapy, particularly to the mucosal barrier. Palifermin, which is a recombinant human keratinocyte growth factor, is FDA-approved (60μg/kg/day administered as an IV bolus injection for 3 consecutive days before therapy and 3 consecutive days after therapy for leukemia or lymphoma) to decrease the incidence or duration of severe oral mucositis.[A2] Avasopasem (a superoxide dismutase mimetic at 90mg given before each therapy) can reduce mucositis in patients who receive radiation therapy for head and neck cancer.[A3] Oral glutamine[A4] and zinc[A5] have shown some benefit for reducing the severity of radiation-induced oral mucositis. However, no medications have been consistently effective for reducing the gastrointestinal side effects of pelvic radiotherapy.[A6]

For radiotherapy-induced dermatitis, mucositis, and xerostomia, treatments include topical agents for dermatitis (Chapter 405), analgesics for mucositis, and saliva substitutes for xerostomia. Beyond dermatitis, mucositis, and xerostomia, radiation-induced deterministic tissue effects are typically treated in the same way as their non-radiation-induced counterparts. For example, the treatment of radiation-induced coronary artery disease is no different than the approach to coronary diseases in general (Chapters 56 to 59). However, the management of acute and chronic gastrointestinal symptoms after radiotherapy requires a more specialized approach because of the risk for local stricture (Chapter 128).

PREVENTION

Countermeasures after Radiologic Accidents or Terrorism

Three FDA-approved pharmaceuticals can limit the radiation dose caused by exposures to specific radioisotopes: potassium iodide for radioactive iodine; Prussian blue for radioactive cesium or thallium; and diethylenetriamine pentaacetate (DTPA) for plutonium, americium, or curium. Although these pharmaceutical countermeasures can limit the organ doses and therefore the health consequences produced by these specific radioisotopes, they cannot be used to treat any of the adverse clinical effects caused by them.

The administration of potassium iodide (KI), which contains nonradioactive iodine, saturates the thyroid with nonradioactive iodine and thereby prevents radioactive iodine from being absorbed into the thyroid, where it can cause thyroid cancer (Chapter 207). The protective effects of KI last about 24 hours, so it should be taken daily (130 mg for adults, 65 mg for children >3 years of age, 32 mg for children 1 to 3 years of age, 16 mg for infants) while there is a likelihood of exposure.

Prussian blue (Radiogardase: ferric hexacyanoferrate [II]) binds cesium in the gastrointestinal tract and limits its reabsorption into the blood stream, thereby reducing the biologic half-life of cesium in the body from about 110 days to about 30 days and limiting the organ toxicities that it produces. The recommended dose of Prussian blue is 3 g orally three times daily for adults and 1 g orally three times daily for children 2 to 12 years of age, for a minimum of 30 days.

DTPA is a chelating agent that binds to radioactive plutonium, americium, and curium, thereby decreasing their persistence in the body. DTPA comes in two forms, Ca-DTPA and Zn-DTPA, with the calcium form considered more effective over the first 24 hours of exposure, and the zinc form preferable at later times, although both are effective over several weeks. They are administered intravenously (or with a nebulizer), with a daily intravenous dose of 1 g for adults and 14 mg/kg for children younger than 12 years.

Several radiation countermeasure drugs have been developed to counteract the symptoms of acute radiation syndromes, have been demonstrated effective in animal models, and are undergoing trials prior to FDA approval.

Medical Imaging

CT is a superb diagnostic tool, and individual CT radiation–associated risks are small; as a result, a great majority of the approximately 90 million CT scans performed annually in the United States generally provide far more benefits than risks. However, organ doses from CT are typically far larger than those from conventional radiographic examinations, so CT should operate under the dual principles of optimization and justification. Optimization involves reducing the radiation dose per CT, using improved protocols and technology.

In terms of justification—making sure that all CT scans are clinically justified, a substantial proportion of CT scans could potentially be replaced by other modalities, such as magnetic resonance imaging for some head examinations and selective use of ultrasound for diagnosing appendicitis. For example, CT scans performed in patients who undergo appendectomy are associated with about a 25% higher risk of subsequent hematologic malignancy.[16] In addition, many CT scans could be avoided entirely by following usage appropriateness criteria.

NON-IONIZING RADIATION INJURY

Ionizing radiations uniquely have sufficient energy to cause DNA strand breaks, which in turn can lead to cell killing and mutations. By contrast, non-ionizing radiations, such as radio waves, microwaves, infrared radiation, and visible light, do not have sufficient energy to break DNA strands, and none of these radiations have been associated with health hazards. One exception is ultraviolet (UV) radiation, which is generally a mutagen and a carcinogen. A second possible exception is radiofrequency radiation, although in this case the epidemiologic evidence and mechanistic considerations do not provide strong evidence of health risks.

ULTRAVIOLET RADIATION

UV radiations, which are part of the non-ionizing electromagnetic spectrum, cover a wavelength from about 150 to 400 nm (intermediate between visible light and x-rays). In turn, these UV wavelengths are subcategorized as UVA (400 to 320 nm), UVB (315 to 280 nm), and UVC (280 to 150 nm).

Sunlight is by far the largest source of UV radiation to humans. Because of filtering in the atmosphere, about 95% of the UV spectrum that reaches the earth's surface is UVA, the remainder is nearly all UVB, and almost no UVC penetrates the ozone layer to reach the earth. Other sources of UV exposures include tanning beds and booths. Industrial exposures include welding arcs, plasma torches, germicidal and blacklight lamps, electric arc furnaces, hot-metal operations, mercury-vapor lamps, and some lasers.

PATHOBIOLOGY

UV radiations do not penetrate deeply into human tissues, so the injuries they cause are principally to the skin and eyes. The biologic effects of UV radiation are primarily attributable to its absorption in DNA, where pyrimidine dimers and their products are produced. These products are generally very efficiently removed, primarily through nucleotide excision repair but also through base excision repair, but errors in these repair processes ultimately can result in mutations. Although most UV radiation in sunlight is UVA, UVB is much more efficiently absorbed by nucleic acids, and most of the biologic effects of sunlight are associated with UVB.

The damaging effects of UV radiation are exacerbated in patients who have underlying defects in nucleotide excision repair. For example, studies of patients with xeroderma pigmentosum have provided key evidence of the link between UV light and skin cancer. In addition, the effects of UV are often enhanced in patients who are taking medications that contain photodynamic agents, such as tetracyclines, fluoroquinolones, nonsteroidal anti-inflammatory drugs, diuretics, statins, phenothiazines, thioxanthenes, and antifungals. Such drug-related phototoxic reactions typically resolve after the drug is discontinued.

CLINICAL MANIFESTATIONS

The major acute effects of UVB exposure are sunburn and erythema, whereas UVA exposure is rarely the direct cause of sunburn. All UV radiations are well-established skin carcinogens (Chapter 188). Squamous cell carcinomas and basal carcinomas are typically associated with multiple or chronic exposures to sunlight, whereas melanoma is linked primarily to episodes of acute sunburn. Lighter-skinned individuals, whose skin and eyes contain less melanin, are more prone to all UV effects because melanin acts as a photoprotector. Acute exposures of the eye to UVB (Chapter 391) can cause "welder flash" (photokeratitis), and chronic exposures are associated with cataracts as well as pterygium.

PREVENTION

Excessive exposure to sunlight or other sources of UV radiation should be avoided, especially in fair-skinned individuals. UV radiation–screening lotions or creams and UV radiation–blocking sunglasses should be used when appropriate.

During significant exposure to sunlight, it is important to use a broad-spectrum sunscreen that provides protection from UVB as well as UVA. Standard recommendations are use of sunscreen with a sun protection factor (SPF) of 30, with reapplication at least every 2 hours. Likewise, sunglasses should be rated to block 99% or 100% of UVB and UVA radiation.

FAR-UVC RADIATION

A particular UV wavelength, far UVC (207 to 222 nm), is an effective antibactericidal and antiviral agent, including against severe acute respiratory syndrome coronavirus 2 (Chapter 336).[17] Because of its very limited penetration, it may be safe for human exposure, unlike typical UVC radiation.

RADIOFREQUENCY RADIATIONS

Radiofrequency radiations are also part of the non-ionizing electromagnetic spectrum (E-Fig. 18-1). Examples are radiation emitted from mobile phones (800 to 2000 MHz),[18] electric power lines (50/60 Hz),[19] low-frequency magnetic fields,[20] and airport whole-body scanners (24 to 30 GHz). Biologic studies of these low-level radiofrequency exposures have generally not shown measurable genotoxicity.

Numerous epidemiologic studies have focused on the effects of electric power line proximity and of cell phone usage. Although some early studies showed positive associations between exposure and health detriment, these studies have generally not proved consistent or repeatable. Further studies are, however, warranted, and an ongoing prospective European study is following 290,000 adult cell phone users over a 20-year period.

In terms of justification—making sure that all CT scans are clinically justified, a substantial proportion of CT scans could potentially be replaced by other modalities, such as magnetic resonance imaging for some head examinations and selective use of ultrasound for diagnosing appendicitis. For example, CT scans performed in patients who undergo appendectomy are associated with about a 25% higher risk of subsequent hematologic malignancy.[16] In addition, many CT scans could be avoided entirely by following usage appropriateness criteria.

NON-IONIZING RADIATION INJURY

Ionizing radiations uniquely have sufficient energy to cause DNA strand breaks, which in turn can lead to cell killing and mutations. By contrast, non-ionizing radiations, such as radio waves, microwaves, infrared radiation, and visible light, do not have sufficient energy to break DNA strands, and none of these radiations have been associated with health hazards. One exception is ultraviolet (UV) radiation, which is generally a mutagen and a carcinogen. A second possible exception is radiofrequency radiation, although in this case the epidemiologic evidence and mechanistic considerations do not provide strong evidence of health risks.

ULTRAVIOLET RADIATION

UV radiations, which are part of the non-ionizing electromagnetic spectrum, cover a wavelength from about 150 to 400 nm (intermediate between visible light and x-rays). In turn, these UV wavelengths are subcategorized as UVA (400 to 320 nm), UVB (315 to 280 nm), and UVC (280 to 150 nm).

Sunlight is by far the largest source of UV radiation to humans. Because of filtering in the atmosphere, about 95% of the UV spectrum that reaches the earth's surface is UVA, the remainder is nearly all UVB, and almost no UVC penetrates the ozone layer to reach the earth. Other sources of UV exposures include tanning beds and booths. Industrial exposures include welding arcs, plasma torches, germicidal and blacklight lamps, electric arc furnaces, hot-metal operations, mercury-vapor lamps, and some lasers.

PATHOBIOLOGY

UV radiations do not penetrate deeply into human tissues, so the injuries they cause are principally to the skin and eyes. The biologic effects of UV radiation are primarily attributable to its absorption in DNA, where pyrimidine dimers and their products are produced. These products are generally very efficiently removed, primarily through nucleotide excision repair but also through base excision repair, but errors in these repair processes ultimately can result in mutations. Although most UV radiation in sunlight is UVA, UVB is much more efficiently absorbed by nucleic acids, and most of the biologic effects of sunlight are associated with UVB.

The damaging effects of UV radiation are exacerbated in patients who have underlying defects in nucleotide excision repair. For example, studies of patients with xeroderma pigmentosum have provided key evidence of the link between UV light and skin cancer. In addition, the effects of UV are often enhanced in patients who are taking medications that contain photodynamic agents, such as tetracyclines, fluoroquinolones, nonsteroidal anti-inflammatory drugs, diuretics, statins, phenothiazines, thioxanthenes, and antifungals. Such drug-related phototoxic reactions typically resolve after the drug is discontinued.

CLINICAL MANIFESTATIONS

The major acute effects of UVB exposure are sunburn and erythema, whereas UVA exposure is rarely the direct cause of sunburn. All UV radiations are well-established skin carcinogens (Chapter 188). Squamous cell carcinomas and basal carcinomas are typically associated with multiple or chronic exposures to sunlight, whereas melanoma is linked primarily to episodes of acute sunburn. Lighter-skinned individuals, whose skin and eyes contain less melanin, are more prone to all UV effects because melanin acts as a photoprotector. Acute exposures of the eye to UVB (Chapter 391) can cause "welder flash" (photokeratitis), and chronic exposures are associated with cataracts as well as pterygium.

PREVENTION

Excessive exposure to sunlight or other sources of UV radiation should be avoided, especially in fair-skinned individuals. UV radiation–screening lotions or creams and UV radiation–blocking sunglasses should be used when appropriate.

During significant exposure to sunlight, it is important to use a broad-spectrum sunscreen that provides protection from UVB as well as UVA. Standard recommendations are use of sunscreen with a sun protection factor (SPF) of 30, with reapplication at least every 2 hours. Likewise, sunglasses should be rated to block 99% or 100% of UVB and UVA radiation.

FAR-UVC RADIATION

A particular UV wavelength, far UVC (207 to 222 nm), is an effective antibactericidal and antiviral agent, including against severe acute respiratory syndrome coronavirus 2 (Chapter 336).[17] Because of its very limited penetration, it may be safe for human exposure, unlike typical UVC radiation.

RADIOFREQUENCY RADIATIONS

Radiofrequency radiations are also part of the non-ionizing electromagnetic spectrum (E-Fig. 18-1). Examples are radiation emitted from mobile phones (800 to 2000 MHz),[18] electric power lines (50/60 Hz),[19] low-frequency magnetic fields,[20] and airport whole-body scanners (24 to 30 GHz). Biologic studies of these low-level radiofrequency exposures have generally not shown measurable genotoxicity.

Numerous epidemiologic studies have focused on the effects of electric power line proximity and of cell phone usage. Although some early studies showed positive associations between exposure and health detriment, these studies have generally not proved consistent or repeatable. Further studies are, however, warranted, and an ongoing prospective European study is following 290,000 adult cell phone users over a 20-year period.

ABSTRACT

Although a terrorist or criminal may seek to use a number of infectious pathogens or toxins to cause illness or disability of humans, certain pathogens have properties that make them potentially better suited to cause large numbers of casualties when released on a population. These properties include the ability to be grown in large quantities, stability in the air, stability for storage, and ease of infection by the aerosol route. Of these potential pathogens or toxins, six have been deemed the highest potential threats if utilized properly: anthrax, smallpox, plague, tularemia, botulism, and viral hemorrhagic fevers. This chapter discusses these specific agents.

smallpox

care providers, dispersed in space and time due to the pathogen's incubation period. One way in which a bioterror attack might differ from a natural outbreak is in the unusual presentation of illness. For example, a disease that typically occurs on the skin or causes gastrointestinal illness might instead exhibit respiratory features (e.g., anthrax, plague). Another clue could be illnesses that are unresponsive to standard therapies because of an unusual antibiotic sensitivity profile. Suspicion should also be raised by finding a disease outside the location or season in which it typically occurs.

AGENTS OF CONCERN

Among the myriad human infectious pathogens, a relatively small number possess the requisite properties to be considered potential weapons that could cause widespread disease, so-called weapons of mass destruction. The U.S. Centers for Disease Control and Prevention (CDC) has designated six as category A due to their ability to cause large-scale disruption, the need for preparedness, and fear their release might engender (Table 19-2).[3] These agents can be formulated to remain stable in aerosol, which allows their potential efficient spread via the air over a large population.

TABLE 19-1 EPIDEMIOLOGIC CLUES OF A BIOWEAPON ATTACK

A large outbreak, especially in a discrete population
Many cases of unexplained illness or deaths
More severe disease than expected for a specific pathogen or failure to respond to standard therapy
Unusual manifestation of illness, such as inhalational disease from agents not typically causing clinical illness
An unusual disease for a given geographic area or transmission season, especially in the absence of a competent vector
Multiple simultaneous or serial epidemics
A single case of a rare disease (smallpox, some viral hemorrhagic fevers, inhalational anthrax, pneumonic plague)
Unusual strains or variants of organisms, or antimicrobial resistance patterns different from those known to be circulating
Higher attack rates among those outside a protected area or lower rates among those inside a protected area or shelter
Outbreaks of the same disease occurring simultaneously in noncontiguous areas
A zoonotic disease occurring in humans but not in animals
Direct evidence or intelligence of a release (equipment, munitions, tampering) or other identified vehicle of spread (spray device, contaminated letter)
A downwind pattern of casualty location

ANTHRAX

EPIDEMIOLOGY

Anthrax, caused by infection with the gram-positive bacillus *Bacillus anthracis* (Chapter 272), is a worldwide scourge of herbivores. Most human cases have had direct occupational contact with infected animals or their hides, hair, or bone, although a recent outbreak occurred among injection drug users in the United Kingdom. Endemic areas include underdeveloped parts of sub-Saharan Africa and Southeast Asia, where humans interact closely with animals that have not been vaccinated. Sporadic cases occur in the United States, typically along the trails of the historic cattle drives in the central plains. Animals are typically infected while grazing in areas contaminated with anthrax spores, which can survive in the soil for decades and can be formulated as a stable desiccated powder. Although most cases worldwide are cutaneous, the spore form of the organism can be milled into the ideal particle size (2 to 6 μm) for infecting the lungs and causing inhalational disease.

PATHOBIOLOGY AND CLINICAL MANIFESTATIONS

Exposure to spores can occur through a break in the skin, through the gastrointestinal tract, or by inhalation. Spores are taken up by macrophages and replicate in the local skin, or are transported to the regional lymph nodes in the gastrointestinal tract or lungs. While replicating, the bacilli secrete lethal toxin, which causes local necrosis, and edema toxin, which causes significant local edema. Untreated or unrecognized infection can result in bacteremia, systemic toxemia, and death.

Cutaneous anthrax can be readily recognized by the astute clinician based on two clinical manifestations caused by its toxins: a black eschar, from which anthrax gets its name (from the Greek *anthrakis*, for coal), and surrounding edema that is out of proportion to the size of the lesion. The lesion starts as a papule that becomes a vesicle and eventually develops a central, black, necrotic area. Although this form of disease is readily treatable, it can lead to a 20% case-fatality rate if it is not recognized and treated appropriately. Gastrointestinal anthrax, which occurs after ingestion of infected, undercooked meat, is much more difficult to recognize and can have a case-fatality rate

TABLE 19-2 CENTERS FOR DISEASE CONTROL AND PREVENTION CATEGORY A BIOTERROR AGENTS

DISEASE (AND AGENT)	DIAGNOSTIC ASSOCIATIONS	WEAPONIZATION RATIONALE	TREATMENT* (SEE TEXT FOR DETAIL)
Anthrax (*Bacillus anthracis*; Chapter 272)	Hemorrhagic mediastinitis	Highly lethal inhalational disease; stable spores survive desiccation; can be formulated as aerosol	**Ciprofloxacin** (400 mg q8h) or (a) levofloxacin (750 mg q24h) or moxifloxacin (400 mg q24h) plus either (b) **meropenem** (2 g q8h) or imipenem (1 g q6h) or doripenem (500 mg q8h) plus (c) **linezolid** (600 mg q12h) or clindamycin (900 mg q8h) or rifampin (600 mg q12h) or chloramphenicol (1 g q6-8h)†
Smallpox (variola virus; Chapter 343)	Synchronous exanthem	Virions stable in environment; population immunologically naïve	Supportive care; brincidofovir and tecovirimat are now licensed treatments
Plague (*Yersinia pestis*; Chapter 288)	Hemoptysis	Contagious through respiratory droplets; "Black Death" conjures fear	Gentamicin (5 mg/kg qd) or ciprofloxacin (400 mg q12h), doxycycline (200 mg × 1, then 100 mg q12h), or levofloxacin 500 mg q24h or moxifloxacin 400 mg q24h
Tularemia (*Francisella tularensis*; Chapter 287)	Plague-like illness	Bacteria stable in environment; very low infectious dose	Same as for plague‡
Botulism (botulinum toxins; Chapter 271)	Descending, flaccid paralysis	Highly potent toxin; lends itself to food and water use; cases consume vast resources	Supportive care; ventilator support; botulinum antitoxin may halt (but will not reverse) symptom progression
Viral hemorrhagic fevers (Chapter 351; see E-Table 19-1)	Hemorrhagic diatheses	Fear factor is paramount; few countermeasures exist	Supportive care; ribavirin may be beneficial in select cases (e.g., Lassa fever, New World arenaviruses, Crimean-Congo hemorrhagic fever virus, hemorrhagic fever renal syndrome) when it is given under an experimental protocol: 30 mg/kg load, then 16 mg/kg q6h for 4 days, then 8 mg/kg q8h for 6 days; for Ebola virus (Zaire), two approved therapies are either REGN-EB3 or mAb114

*All therapeutic agents listed in this table should be administered intravenously.
†Preferred treatments are in **bold**.
‡Note that levofloxacin and moxifloxacin are now licensed by the U.S. Food and Drug Administration for the treatment of plague, but not for tularemia.
qd = once daily.

of 50% or more. Reported in the United States for the first time after an animal-hide drum circle event in 2009, the disease causes fever, abdominal pain, diarrhea, hematochezia, hematemesis, and ascites. Paracentesis may yield hemorrhagic ascites.

Inhalational anthrax is of greatest concern after an aerosolized bioweapon attack. After an incubation period that averages 1 to 6 days but can be up to 43 days, patients present with fever, profound drenching sweats, nausea, vomiting, diarrhea, shortness of breath, cough, and chest pain. Without prompt recognition and appropriate therapy, individuals can deteriorate rapidly with increasing dyspnea, stridor, cyanosis, and respiratory failure. Engorgement and hemorrhage of mediastinal lymph nodes with accompanying mediastinitis lead to the clinical hallmark of a widened mediastinum on the chest radiograph in about 60% of cases. Patients may also develop large hemorrhagic pleural effusions and infiltrates. Bacteremic dissemination can lead to widely metastatic infection in the gastrointestinal tract and meninges.

DIAGNOSIS

B. anthracis can be identified by Gram stain or culture of tissue or body fluids, including skin biopsy for cutaneous disease, peripheral blood, pleural effusions, and cerebrospinal fluid but not sputum. A chest radiograph may provide initial clues to inhalational disease with manifestations such as hilar or paratracheal fullness and pleural effusions. A chest computed tomography scan can confirm mediastinal adenopathy. Other techniques, such as fluorescent antibody staining or polymerase chain reaction (PCR), may provide more rapid diagnosis.

TREATMENT

The approach to the management of patients[4] infected with or exposed to anthrax differ among patients with meningitis and patients in whom meningitis has been excluded. For patients in whom meningitis is present or cannot be excluded, three antibiotics are administered intravenously (preferred drugs are in bold):

- **Ciprofloxacin** (400 mg q8h) or levofloxacin (750 mg q24h) or moxifloxacin (400 mg q24h) plus
- **Meropenem** (2 g q8h) or imipenem (1 g q6h) or doripenem (500 mg q8h) plus
- **Linezolid** (600 mg q12h) or clindamycin (900 mg q8h) or rifampin (600 mg q12h) or chloramphenicol (1 g q6-8h).

If meningitis has been excluded, a two-drug regimen can be used:

- **Ciprofloxacin** or levofloxacin or moxifloxacin or meropenem or imipenem or doripenem or vancomycin (penicillin G or amoxicillin can also be used if the infecting strain is known to be susceptible) plus
- **Clindamycin or linezolid** or doxycycline or rifampin

A monoclonal antibody, raxibacumab (single dose of 40 mg/kg IV during 2 hours and 15 minutes after premedicating with diphenhydramine 25 to 50 mg IV), is approved for additional therapy of inhalational anthrax along with antibiotics on the basis of animal efficacy data. Intravenous anthrax immune globulin, which has been given as adjunctive therapy to a small number of patients, is approved in the United States for use in addition to antibiotics for inhalational anthrax. Another antibody, obiltoxaximab (16 mg/kg IV), is also approved by the Food and Drug Administration (FDA) to treat inhalational anthrax in combination with appropriate antibacterial drugs or to prevent inhalational anthrax based on its efficacy in animals and safety in healthy human volunteers.[5]

PREVENTION

The anthrax vaccine,[6] which is effective at preventing all forms of disease, has been reserved primarily for at-risk ranchers or veterinarians who have regular contact with herbivores, as well as for laboratory research personnel and military personnel. The vaccine is given as five doses intramuscularly over 18 months (day 0, followed by 1, 6, 12, and 18 months), with annual boosters if continued risk exists.

After a known exposure, chemoprophylaxis is recommended with ciprofloxacin (500 mg orally twice daily) or doxycycline (100 mg orally twice daily) for 60 days, although shorter durations are likely to be effective, especially if combined with vaccination. If the vaccine is available, three doses may be given concomitantly with antibiotics, but it is not licensed for this purpose and must be administered under an investigational protocol. Raxibacumab (dosed as before) is also approved for prophylaxis if antibiotics are not available.[7]

PROGNOSIS

Factors associated with survival from anthrax include administration of a multiple-drug antibiotic regimen or anthrax antiserum given during the prodromal phase, as well as pleural fluid drainage. Case-fatality rates in untreated patients approach 100%, although 55% of the victims of inhalation anthrax survived in a 2001 outbreak, likely owing to the use of multiple antibiotics and modern intensive care.

SMALLPOX

EPIDEMIOLOGY

Although smallpox was declared eradicated in 1980, concerns exist about undeclared stores outside approved repositories in the United States and Russia. The recent discoveries of unaccounted for vials of variola in the United States provide some credence to this concern. In addition to near-universal susceptibility, the environmental stability of smallpox viral particles makes it a formidable potential weapon.[8]

Smallpox is caused by variola virus, an orthopoxvirus (Chapter 343) that is closely related to cowpox, vaccinia, monkeypox, and Alaskapox. Variola generally spreads to household and other close contacts, but it can spread via aerosolized droplet nuclei as well as by direct contact with patient secretions or fomites. Health care providers who are caring for patients or unsuspecting individuals who have contact with contaminated objects are also at risk.

PATHOBIOLOGY AND CLINICAL MANIFESTATIONS

Infection initially occurs in the respiratory mucosa, is followed by replication in the regional lymph nodes, and leads to an asymptomatic primary viremia that seeds the reticuloendothelial system. Approximately 1 week after infection (range, about 1 to 2 weeks), a secondary viremia seeds the skin. At this time, the sudden onset of illness includes fever, headache, backache, and vomiting. Within 2 or 3 days of this prodrome, and often as the temperature falls, the characteristic rash begins with small papules in a centrifugal pattern (more on the face and extremities than on the trunk) that progress in synchronous fashion during the next week to vesicles, umbilicated pustules, and finally scabs. Lesions are deep seated and can be intensely painful. Individuals are contagious at the onset of the rash and are considered free of contagion only after the scabs have separated.

DIAGNOSIS

Chickenpox (varicella; Chapter 346), which might be confused with early or mild smallpox, occurs predominantly on the trunk rather than on the extremities (a centripetal pattern), and the lesions occur in successive crops, so macules, papules, pustules, and scabs can be seen simultaneously. In addition, varicella is transmissible before onset of the rash, but contagiousness abates when all the lesions are scabbed. Other diseases in the differential diagnosis of smallpox include monkeypox (Chapter 343), Alaskapox, other poxviruses, disseminated vaccinia in a vaccine recipient or contact, disseminated herpes zoster (Chapter 346) or herpes simplex (Chapter 345), impetigo (Chapter 408), drug eruptions (Chapter 407), contact dermatitis (Chapter 405), erythema multiforme (Chapter 406), and rickettsialpox (Chapter 302).

Clinical recognition of the characteristic rash (Fig. 19-1) should raise suspicion of smallpox. Diagnosis would likely come from PCR or viral culture of skin or blood samples or from acute and convalescent serologies.

TREATMENT

The primary therapy for smallpox remains supportive care, although tecovirimat (600 mg orally every 12 hours for 14 days) is approved by the U.S. FDA to treat all poxvirus infections and is included in the strategic national stockpile.[9] Brincidofovir (4 mg/kg, once weekly for two doses, maximum 200 mg), which is an oral analog of cidofovir, is also an approved treatment.

PREVENTION

Vaccination uses vaccinia, an orthopoxvirus related to variola. In the event of an outbreak, postexposure vaccination within 4 days can prevent or ameliorate disease and might be applied in a method of surveillance and containment, as was used during global eradication. The U.S. government has stockpiled enough doses for the entire U.S. population of a live replicating cell-culture-derived product (ACAM2000) for use in a national emergency. The surveillance and containment, or ring, vaccination method combines active case finding with vaccination of potential contacts within a certain radius around the cases. Health care providers would need to be vaccinated, and airborne

FIGURE 19-1. **Smallpox. A**, Demonstrates centrifugal nature of the rash. **B**, Demonstrates coalescences of some pustules. **C**, Demonstrates umbilicated pustules. (From Fenner F, Henderson DA, Arita A, et al. *Smallpox and its Eradication*. Geneva: World Health Organization; 1988.)

and contact precautions (HEPA filter masks, negative-pressure rooms, gowns, gloves, eye protection) would be recommended in the hospital environment. Because the vaccine is a live agent, it is contraindicated in individuals who are immunocompromised and in individuals who have eczema or significant exfoliative skin conditions. Even in normal hosts, the vaccine can be associated with inoculation of other locations on the body, spread to close contacts, disseminated disease, postvaccine encephalitis, progressive vaccinia in individuals with defective cell-mediated immunity, eczema vaccinatum in people with prior eczema, and pericarditis or myocarditis.[10] In the postexposure setting, risks and benefits must be weighed regarding which individuals at risk for complications might receive vaccine and whether vaccinia immune globulin might be administered concomitantly. First-line therapy for significant vaccine reactions is vaccinia immune globulin. A novel live, but nonreplicating, vaccinia-based vaccine, Jynneos, was recently approved by the FDA for the prevention of smallpox as well as monkeypox. Although this product is expected to alleviate some of the concerns associated with the replicating vaccine, its requirement for two doses would complicate its use in a postexposure setting.[A1]

PROGNOSIS

The case-fatality rate for the typical form of smallpox, variola major, is approximately 30%, but wide variations exist. In the minority of individuals who develop hemorrhagic smallpox or flat-type smallpox, the case-fatality rate approaches 100%. A different viral strain, variola minor, has case-fatality rates of only about 1%. Survivors of smallpox are often left with lifelong scarring from the lesions. Blindness and bone deformities, especially in children, are also known complications.

PLAGUE

EPIDEMIOLOGY

Plague, which is caused by the gram-negative coccobacillus *Yersinia pestis* (Chapter 288), was responsible for hundreds of millions of deaths during three historic pandemics. Plague was used as a weapon by the Japanese before World War II when they released infected fleas in Chinese cities, and it was included in the former Soviet Union's biologic weapon arsenal. Plague is transmissible through the respiratory route, so an aerosol release could have devastating effects.

Each year in the United States, several human cases are reported, usually in the Southwest. Most of these cases are bubonic, although occasional pneumonic plague has been linked to infections in domestic cats.

PATHOBIOLOGY AND CLINICAL MANIFESTATIONS

Plague is manifested in three ways.[11] Bubonic plague, which is the most common form, occurs after the bite of an infected flea. The organism spreads through the local lymphatics to the regional lymph nodes. As replication occurs, the lymph node or group of lymph nodes becomes swollen and extremely tender. Because most flea bites occur on the lower extremities, the inguinal and femoral lymph nodes are most often affected. Untreated bubonic plague can progress to septicemic plague after organisms gain entry to the blood stream. In addition, patients can develop necrosis of cooler areas of the body, such as the tip of the nose, ears, or digits, due to a temperature-dependent coagulase produced by the organism.

Septicemic plague may also occur in the absence of an antecedent bubo. Meningitis may occur from seeding through the blood stream.

In pneumonic plague, the lungs are seeded secondarily by bacteremia from septicemic plague or primarily when a person inhales infectious droplets. Although naturally occurring pneumonic plague is rare, this form of disease is the major concern after intentional release of aerosol. In patients with pneumonic plague, the disease can be spread to others. One of the hallmarks of the disease is the potential for purulent sputum to become hemorrhagic. Although hemoptysis can certainly be seen with other diseases (Chapter 71), the presentation of clusters of multiple patients with hemoptysis should prompt the clinician to consider plague.

DIAGNOSIS

Plague bacilli are readily identified by their bipolar appearance or Gram, Wright-Giemsa, or Wayson stains, and they can be cultured from sputum or other infected body fluid, such as blood, fluid from a bubo, or cerebrospinal fluid. Other diagnostic methods include PCR for the F1 antigen, direct fluorescent antibody staining of body fluids, and serology by enzyme-linked immunosorbent assay or passive hemagglutination. However, serology is primarily useful in retrospect, because patients must be treated empirically before a serologic response occurs.

TREATMENT

Drug options include streptomycin (if available, 1 g IM twice daily for 7 to 10 days or for 3 days after the fever remits) or gentamicin (5 mg/kg IM or IV daily or a 2-mg/kg load followed by 1.7 mg IM or IV three times daily also for 7 to 10 days). Alternative choices (all for 7 to 10 days or for 3 days after fever and symptoms have resolved) include doxycycline (200-mg IV load, then 100 mg IV every 12 hours), ciprofloxacin (400 mg IV every 12 hours), levofloxacin (500 to 750 mg IV once daily), and moxifloxacin (400 mg IV once daily) (Table 19-2).[12] The drug of choice for plague meningitis is chloramphenicol (25- to 30-mg/kg IV load, followed by 50 to 60 mg/kg/day every 6 hours; on favorable clinical response, the dose can be reduced to 25 to 30 mg/kg/day every 6 hours). CDC now recommends the addition of either levofloxacin (750 mg once daily) or moxifloxacin (400 mg once daily) to chloramphenicol, when feasible.

PREVENTION

Use of standard precautions is appropriate for bubonic plague. Droplet precautions should be applied for patients with pneumonic plague, including a private room where caregivers wear masks, gowns, gloves, and eye protection within 3 to 6 feet of the patients. These precautions should be continued until the patient demonstrates improvement and has been receiving effective antibiotics for 72 hours. Oral ciprofloxacin (500 to 750 mg twice daily), levofloxacin (500 to 750 mg once daily), doxycycline (100 mg twice daily), or moxifloxacin (400 mg once daily) is recommended for postexposure prophylaxis for 7 days beyond the period of exposure in household contacts or individuals suspected of exposure in either the endemic or bioterrorism setting.[13]

No licensed vaccine for plague currently exists in the United States, and a previously licensed whole-cell killed vaccine is no longer available. New vaccines are being studied.

PROGNOSIS

Case-fatality rates are 50% or more for untreated bubonic plague and nearly 100% for untreated septicemic and pneumonic plague. These fatality rates can be significantly reduced with prompt recognition and appropriate therapy.

TULAREMIA

Tularemia (Chapter 287) is caused by infection with the gram-negative, aerobic nonmotile coccobacillary organism *Francisella tularensis*.[14] A zoonotic disease of rabbits, ground squirrels, and other small mammals, tularemia can infect humans by skin or mucous membrane contact with body fluids or tissues of infected animals or from the bite of infected deerflies, mosquitoes, or ticks. Disease rarely occurs by inhalation of contaminated dusts or ingestion of contaminated food or water. One outbreak was associated with groundskeepers in Martha's Vineyard. Fewer than 150 cases of naturally occurring human tularemia are typically reported each year. However, the environmental stability of *F. tularensis* as well as its very low infectious dose (as few as 10 organisms) makes it a potential weaponization threat.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Clinical manifestations of tularemia depend on the route of exposure. Although six different forms have been described, tularemia is perhaps more simplistically compared with plague, with glandular forms analogous to bubonic plague, as well as pneumonic and typhoidal forms that present a clinical picture similar to what is seen in pneumonic and septicemic plague. A preponderance of these latter forms would be expected after an intentional release by aerosol. After an incubation period of 2 to 10 days, symptoms begin with fever and proceed to include severe exhaustion, substernal chest pain, nonproductive cough, and weight loss.

A diagnosis can be made by isolating the organism from blood, sputum, skin, or mucus membrane lesions, but culture may be difficult because of unusual growth requirements and overgrowth of commensal organisms. Molecular technologies are available in specialized laboratories, but serology is the most common method of diagnosis, often in retrospect. Because of the risk of spread to microbiology laboratory personnel, it is important to notify the laboratory if infection with this organism is suspected.

TREATMENT AND PROGNOSIS

Treatment of tularemia is similar to that of plague, with aminoglycosides for 7 to 10 days; streptomycin and gentamicin are considered the drugs of choice, although ciprofloxacin is a newer potential alternative (Table 19-2). Doxycycline/tetracycline and chloramphenicol are second-line choices because their use has been associated with relapses, and the recommended duration of therapy is 14 to 21 days.

Person-to-person spread is unusual, and standard precautions are adequate in caring for ill individuals. For known exposures, consensus recommendations in a bioterrorism setting call for doxycycline (100 mg) or ciprofloxacin (500 mg) orally twice a day for 14 days as postexposure prophylaxis. A live attenuated vaccine has proven efficacy in preventing disease due to laboratory exposures and aerosol challenge in human volunteers, but it is not readily available to the public.

The case-fatality rate for untreated pneumonic and typhoidal tularemia is 35%, but this rate can be reduced to less than 5% with appropriate treatment.

BOTULISM

Botulism is caused by exposure to one of eight related neurotoxins (A to H) produced by strains of *Clostridium botulinum* (Chapter 271), a ubiquitous, anaerobic, spore-forming, gram-positive bacillus. Botulinum toxins, which are among the most toxic substances known, can be lethal in doses as low as 0.001 μg/kg. These toxins block release of acetylcholine from presynaptic nerve terminals, thereby resulting in a generalized flaccid paralysis with autonomic dysfunction. Although most toxins are unstable in the environment and thus constitute dubious weaponization threats, the potent nature of botulinum toxin, coupled with the ease with which it might be used to contaminate food and water, makes it a concern. Naturally occurring human botulism is limited to types A, B, and E, although other toxin serotypes can produce an identical clinical syndrome. For this reason, a heptavalent antitoxin with activity against serotypes A to G was licensed in 2013.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Botulism typically develops after a latent period ranging from hours to several days. Initial manifestations involve bulbar palsies, ptosis, photophobia, blurred vision, and other signs of cranial nerve dysfunction.[15] Symptoms progress craniocaudally, thereby leading to dysphonia, dysphagia, and, ultimately, a descending symmetrical paralysis. In fatal cases, death typically results from respiratory muscle failure.

Although botulism may mimic other neurologic disorders, such as myasthenia gravis (Chapter 390) and Guillain-Barré syndrome (Chapter 388), the occurrence of an outbreak involving multiple cases of descending, symmetrical, flaccid paralysis should make diagnosis of botulism relatively straightforward.

TREATMENT AND PROGNOSIS

Supportive care measures, including meticulous attention to ventilatory support, are the mainstay of botulism management. Patients may require such support for several months, so the management of a large-scale botulism outbreak would be resource intensive. Antitoxin should be administered as soon as possible to prevent progressive disease. Botulism is not contagious, so standard precautions are appropriate. The first victims of an outbreak may have higher case-fatality rates because of delays in recognition. Patients who recover can have long-term sequelae, such as dyspnea on exertion, fatigue, and weakness.

VIRAL HEMORRHAGIC FEVERS

EPIDEMIOLOGY

Viral hemorrhagic fever (Chapter 351) describes a clinical syndrome caused by four families of RNA viruses: filoviruses (Ebola and Marburg), arenaviruses ("Old World" Lassa fever and "New World" South American viruses, Machupo, Junin, and others), bunyaviruses (hantaviruses, Crimean-Congo hemorrhagic fever, and Rift Valley fever), and flaviviruses (yellow fever and dengue) (E-Table 19-1). Agents of greatest concern from a bioterrorism perspective include the filoviruses and arenaviruses, which are infectious by the aerosol route, can replicate well in cell culture for large-scale production, and have a clinical syndrome of hemorrhage and fever that engenders fear. The massive outbreak of Ebola virus disease in West Africa in 2013-2016 and a subsequent outbreak in eastern Democratic Republic of the Congo in 2018-2020 demonstrated the devastation that a hemorrhagic fever virus can have on a population, even in the absence of an intentional release, in an environment conducive to spread, including limited medical infrastructure, mobile populations, mistrust of government, and close contact during burial practices, among other factors.[16]

PATHOBIOLOGY AND CLINICAL MANIFESTATIONS

Once virus gains entry through the skin, mucous membranes, or respiratory tract, replication occurs in macrophages and dendritic cells. Organisms are then transported to regional lymph nodes and eventually through the lymphatics and blood stream to target organs, such as the liver and spleen, where local necrosis occurs. The body responds with activation of cytokines and chemokines, and massive depletion of lymphocytes disables the host's adaptive immune response. A sepsis-like picture ensues, with

E-TABLE 19-1 COMPARISON OF VIRAL HEMORRHAGIC FEVER AGENTS*

FAMILY	VIRUS	ENDEMIC AREA	FATALITY RATE	NOSOCOMIAL TRANSMISSION	COUNTERMEASURES
Filoviruses	Ebola	Africa, Philippines (Reston)	18.5-90% (Sudan/ Zaire)	Yes	Reduced fatality rates with supportive care, including fluid and electrolyte management. Two newly licensed monoclonal antibody treatments against Ebola (Zaire) virus. Lower fatality rates occurred in U.S. and European intensive care settings compared with endemic settings. Licensed vaccine (Ervebo).
	Marburg	Africa	23-70%	Yes	
Arenaviruses	Lassa	West Africa	1-2%	Yes	Ribavirin effective in a clinical trial with nonrandomized controls
	Junin	Argentine Pampas	30%	Rare	Immune plasma; reports of benefit with ribavirin; Candid#1 vaccine protective; not available in the United States
	Machupo	Bolivia	25-35%	Rare	Immune plasma; reports of benefit with ribavirin
Bunyaviruses	Crimean-Congo hemorrhagic fever	Africa, southeast Europe, Central Asia, India	30%	Yes	Anecdotal success with ribavirin treatment
	Rift Valley fever	Africa	<0.5%	No	Livestock vaccines in Africa; U.S. Department of Defense has two experimental vaccines
	Hantaviruses	Europe, Asia, South America (rare)	5% (Asian hemorrhagic fever with renal syndrome)	No†	Vaccines available in Asia; ribavirin effective in randomized trial for hemorrhagic fever renal syndrome but not licensed for that purpose
Flaviviruses	Yellow fever	Africa, South America	3-12% (20-50% if second phase develops)	No	17D live attenuated vaccine
	Kyasanur Forest	Southern India	3-5%	No	Formalin-inactivated vaccine in India
	Omsk	Siberia	0.2-3%	No	Tick-borne encephalitis vaccines (not in United States) may offer some cross protection

†Exception is Andes, which causes hantavirus pulmonary syndrome (not addressed in this chapter).

declining mean arterial pressure, increased vascular permeability, and a bleeding diathesis.

Clinical features of the hemorrhagic fevers include the acute onset of malaise, sore throat, fever, skin flushing, conjunctival injection, prostration, myalgias, and nonbloody diarrhea. These viruses have significant differences in the prominence of individual clinical findings. For example, dengue, the filoviruses, and Lassa more commonly cause a maculopapular rash in the first week. The filoviruses and South American viruses more typically cause obtundation and encephalitis. Although all of these viruses produce modest elevations of aminotransferase levels, yellow fever and Rift Valley fever are known for causing significant hepatic dysfunction, thereby resulting in icterus and jaundice. Depending on a number of factors, including virulence, route of exposure, inoculum, and other host factors, illness can progress in the second week to overt signs of bleeding, including petechiae, purpura, ecchymoses, and oozing from venipuncture sites. Electrolyte abnormalities and large-volume gastrointestinal losses were reported during the 2013-2016 West Africa Ebola outbreak. Massive bleeding occurs uncommonly; but if it does, the source is usually the gastrointestinal tract. Severe cases will demonstrate a combination of neurologic and hematologic abnormalities.

DIAGNOSIS

Numerous common diseases should be considered in the differential diagnosis of a viral hemorrhagic fever, including rickettsial infections (Rocky Mountain spotted fever, ehrlichia, anaplasma, and African tick typhus; Chapter 302), leptospirosis (Chapter 298), meningococcemia (Chapter 274), typhoid (Chapter 284), and falciparum malaria (Chapter 316). However, a viral hemorrhagic fever should be considered in patients who present with a clinically compatible syndrome, especially if a cluster of cases is seen.

Laboratory features may include thrombocytopenia, elevated aminotransferase levels, leukopenia, anemia (although an elevated hematocrit may be seen in patients with significant vascular leakage, as is sometimes seen with dengue and hantaviruses), hematuria, and proteinuria.

PCR, viral culture, immunoglobulin M–specific enzyme-linked immunosorbent assay, acute and convalescent serology, or immunohistochemistry on autopsy specimens can establish the diagnosis. Routine clinical specimens and any attempt at viral isolation require a biosafety level 3 or 4 laboratory with expert consultation from the CDC or the U.S. Army Medical Research Institute of Infectious Diseases.

TREATMENT

Two licensed therapies now exist for Ebola virus: Inmazeb (a cocktail of three monoclonal antibodies) and Ebanga (a single monoclonal antibody). Both showed significantly decreased fatality rates in the 2018-2020 outbreak in eastern Democratic Republic of Congo.[A2] Even with this success, however, supportive care remains a primary means of management for all viral hemorrhagic fevers, with close attention to fluid status, electrolytes, avoidance of procedures that cause bleeding and medications that impair platelet function, use of blood products as necessary, use of vasopressors for hypotension, and dialysis for renal failure. Close attention to fluid status has significantly reduced mortality from dengue, and aggressive fluid repletion has been needed to address significant loss of fluid volume due to diarrhea, electrolyte abnormalities, and protein/nutritional depletion in Ebola infections.[17] Oral ribavirin or intravenous ribavirin (see Table 19-2) under an approved experimental protocol can reduce mortality in Lassa hemorrhagic fever and also appears to be beneficial against Argentine hemorrhagic fever (Junin virus) and hantaviruses that cause hemorrhagic fever with renal syndrome. Ribavirin has no apparent efficacy against filoviruses (Ebola or Marburg) or flaviviruses (dengue, yellow fever).

PREVENTION

Vaccines licensed by the U.S. FDA are available against only two specific agents, yellow fever and Ebola.[A3] Experimental vaccines exist against Junin virus and Rift Valley fever virus, but these vaccines have been used primarily to protect laboratory workers.

Certain viral hemorrhagic fevers (primarily Ebola, Marburg, Lassa, and Crimean-Congo hemorrhagic fever) produce high-level viremia during the period of greatest bleeding risk and body fluid production, thereby making them notorious for causing nosocomial outbreaks. In general, these outbreaks occur in environments, such as sub-Saharan Africa, where basic infection control practices are inadequate because of limited resources (e.g., lack of gowns, gloves, and eye protection as well as reuse of unsterilized needles and syringes). Spread of these viruses in the nosocomial environment can be significantly reduced with standard precautions that limit contact with blood and body fluids. In caring for patients who may spread disease, the use of masks, gowns, gloves, and eye protection is recommended. Many cases in the United States and Europe are cared for in biocontainment units specifically designed to reduce nosocomial spread to caregivers.[18]

PROGNOSIS

Hemorrhagic viruses exhibit a wide range of mortality rates, ranging from less than 1% with Rift Valley fever to 80 to 90% with untreated Ebola Zaire (E-Table 19-1). Despite the notoriety of these viruses for causing hemorrhage, the majority of individuals do not die of blood loss. Rather, death results from a sepsis-like picture (Chapter 94), including a loss of vascular hemostasis, disseminated intravascular coagulation, hypotension, renal failure, shock, and death. Provision of intensive care appears to have benefit.

RESPONSE TO A BIOTERRORISM ATTACK

Even a relatively small bioterror event can have profound consequences. After the 2001 anthrax mailings, thousands of people were prescribed antibiotic prophylaxis, and government buildings were closed for decontamination. Since that event, significant improvements in future responses to a bioterrorism event include the licensure, manufacture, and storage of enough smallpox vaccine for everyone in the United States; production of anthrax and botulinum antitoxins for the strategic national stockpile; and development of protocols and authority for response.

The early detection of the release of a pathogen remains a significant challenge. The 2013-2016 Ebola outbreak also identified shortcomings in preparedness, which may be mitigated, in part, by establishing a network of biocontainment units.

A framework for pandemic preparedness, which applies to bioterrorism preparedness as well,[19] includes four main features: ensuring the global community commits appropriate financial resources and monitors progress; reinforcing national public health capabilities and infrastructure; strengthening the leadership role of the World Health Organization; and enhancing the scientific armory against infectious diseases.

Unfortunately, the response to the coronavirus-2019 (COVID-19) pandemic demonstrated that, despite lessons learned from both the 2001 anthrax attacks and the 2013-2016 Ebola outbreak, significant challenges remain in public health preparedness. There is a critical need to reassess our response capability and capacity for the next public health emergency.[20]

In any future bioterror attack,[21] early warning signs might include clusters of patients with mediastinal adenopathy or widened mediastinum on the chest radiograph, a centrifugal pustular rash (smallpox), pneumonia and hemoptysis (plague), descending flaccid paralysis (botulism), or hemorrhagic manifestations and impaired clotting (viral hemorrhagic fever). Should such a cluster be identified or suspected, physicians should contact the local county or city health department, the state health department, and potentially the CDC. Unlike a natural outbreak, a potential bioterror outbreak also requires a rapid dialogue between public health and law enforcement authorities, because patient and environmental samples constitute evidence against a perpetrator and must be handled under chain of custody. Physicians also must be prepared not only to protect themselves and their patients but also to serve as community resources, regardless of whether an outbreak is natural or terrorist in origin.

20 CHRONIC POISONING: TRACE METALS AND OTHERS

LOUISE W. KAO, LAURA TORMOEHLEN, AND BLAKE A. FROBERG

About 80% of the elements in the periodic table are metals or metalloids, and various metals are in contact with humans in the home, workplace, and environment. Metals are part of a number of normal physiologic processes, such as iron in hemoglobin, but also can cause a number of toxic adverse effects.[1–3]

LEAD TOXICITY

EPIDEMIOLOGY

Lead (Pb) is a silver-gray, malleable metal that is resistant to corrosion. It has no known physiologic use, so any lead in the human body should be considered contamination.

The most common sources of lead poisoning are lead-based paints, lead-contaminated dust, and lead-contaminated soil. Other sources include plumbing, solder, batteries, retained bullets, toys, curtain weights, necklace charms, food containers, and cosmetics, including Nigerian eyeliners. Adults in occupations such as battery manufacturing, welding, construction, mining, glass blowing, rifle ranges, and shipbuilding have the highest lead exposures. Other less common but important routes of exposure include lead-contaminated moonshine and lead-containing ethnic folk remedies (e.g., greta and azarcon in Mexico).

Children in lower socioeconomic areas have the highest exposures to lead,[4] and the majority of the scientific literature is biased toward pediatric studies. Much of what we have learned, however, is applicable to adults.

PATHOBIOLOGY

Lead's most devastating effects are on the central nervous system (CNS) of children. By disrupting the intracellular junction of capillary endothelium, lead impairs the blood-brain barrier and further increases its CNS absorption. Lead also increases capillary leak, which in severe cases can result in cerebral edema.

Lead inhibits several enzymes involved in heme synthesis: aminolevulinic acid synthetase, δ-aminolevulinic acid dehydratase, coproporphyrinogen decarboxylase, and ferrochelatase. Lead also inhibits the enzyme erythrocyte pyrimidine-5-nucleotidase and, as a result, impairs RNA degradation and contributes to red cell hemolysis. Collectively, the inhibition of these enzymes results in decreased concentrations of hemoglobin and a shorter lifespan of red blood cells.

By depositing lead-protein complexes in renal proximal tubular cells, lead interferes with normal mitochondrial function, thereby resulting in decreased reabsorption of glucose, amino acids, and phosphate. Chronically exposed persons can develop renal failure from tubular atrophy, interstitial fibrosis, and glomerular sclerosis.

Although lead has not been associated with specific bone-related disorders, the skeletal system serves as the main reservoir for lead; with chronic exposure, lead stores in bone can have a half-life of 5 to 19 years. As a result, tissues may be subjected to increased lead exposure during times of accelerated bone turnover, such as during childhood growth, after fracture of a long bone, or during pregnancy.

CLINICAL MANIFESTATIONS

Lead poisoning can be subtle and difficult to diagnose because many of its historical clinical associations (e.g., neuropathy, gout, abdominal colic) are rarely seen today. In children, the most concerning long-term complications of environmental lead exposure are developmental cognitive deficits, especially when lead concentrations in young children exceed 100 µg/dL. Subacute neurologic problems include ataxia, lethargy, seizures, and coma. Adults can also experience severe neurologic symptoms (e.g., seizures and cerebral edema) with plumbism, but typically only when whole blood lead levels are higher than 150 µg/dL. More commonly, the neurologic problems caused by lead in adults are manifested as memory problems,[5] insomnia, depression, personality changes, and an increased risk of cardiovascular disease. Higher childhood blood levels are also associated with changes on measures of brain structure seen on magnetic resonance imaging (MRI).[6]

Other clinical effects of lead poisoning, in both children and adults, include a normocytic or microcytic anemia, abdominal pain, hepatotoxicity, and pancreatitis. The classic finding of peripheral neuropathy with footdrop and wristdrop is well described in adults but only occasionally seen in children. Nephrotoxicity most commonly is manifested as Fanconi syndrome (Chapter 113) with aminoaciduria, glycosuria, and phosphaturia. A consequence of this toxicity is impaired uric acid clearance and gout (Chapter 252). High lead levels may increase the risk of hypertension.

DIAGNOSIS

Existing evidence is insufficient to recommend screening for elevated blood lead levels in asymptomatic individuals,[7] so the diagnosis of lead intoxication involves a high level of clinical suspicion. The best initial test is a whole blood lead level collected in a certified lead-free tube (Table 20-1). The blood lead level can be falsely elevated in individuals who have received chelation therapy in the prior 7 days. Capillary lead levels can be falsely elevated by skin contaminated with lead.

Radiographic imaging can support the diagnosis of lead poisoning and sometimes detect a lead-containing object or a retained bullet. Bone x-ray fluorescence technology can estimate bone lead levels, which can reflect chronic lead exposure, but this test is not commonly available.

TREATMENT

The first step in the management of patients with elevated lead levels is prompt removal of the source, although the effectiveness of household environmental clean-up and educational initiatives is disappointing.[A1,A2] If lead comes from a work-related source, the Occupational Safety and Health Administration should be contacted. Chelation increases excretion of lead in a 24-hour urine sample and thereby decreases blood concentrations, but studies to date with the chelating agent succimer (2,3-dimercaptosuccinic acid, DMSA) in children have not shown improved neuropsychological function despite success in reducing blood lead levels. The current recommendation is that asymptomatic adults with blood lead levels of less than 70 µg/dL do not require chelation, patients with mild symptoms or blood lead levels between 70 and 100 µg/dL should receive oral chelation, and patients with lead-induced encephalopathy or blood lead levels above 100 µg/dL should receive parenteral chelation. Although DMSA is approved by the Food and Drug Administration only for children, it also is commonly used in adults (Table 20-2).

Whole bowel irrigation with a polyethylene glycol–electrolyte solution should be considered if a patient has retained a gastrointestinal lead object. Patients who have lead-containing bullet fragments lodged in soft tissues or joint spaces may need to have them surgically removed.

PROGNOSIS

Despite controversy about long-term recovery from lead-associated cognitive deficits in children, adults with neurologic symptoms improve with removal of the exposure. The hematologic and nephrotoxic effects of lead also are reversible.

TABLE 20-1 DIAGNOSTIC TESTING FOR METALS: REFERENCE RANGES

METAL	SERUM LEVEL	WHOLE BLOOD LEVEL	SPOT URINE	24-HOUR URINE
Lead		<5 µg/dL		
Mercury		<10 µg/L	<20 µg/L	<5 µg/L creatinine
Arsenic		<5 µg/L		<50 µg/L or <100 µg/g creatinine
Cadmium		<5 µg/L		<3 µg/g creatinine
Aluminum	<2 µg/L	<12 µg/L		<4-12 µg/g creatinine
Bismuth	<1 µg/dL	<5 µg/dL	<20 µg/L	
Cobalt	0.1-1.2 µg/L		0.1-2.2 µg/L	
Manganese	0.4-0.85 µg/L	4-15 µg/L		<10 µg/L
Silver	<0.5 µg/L			<1 µg/L
Thallium		<2 µg/L		<5 µg/L
Zinc	109-130 µg/dL	600-1000 µg/dL		<500 µg/day

Modified from Nelson L, Howland M, et al., eds. *Goldfrank's Toxicologic Emergencies*. 11th ed. New York: McGraw-Hill Medical; 2019.

ABSTRACT

Comprising 80% of the periodic table, heavy metals are an integral part of human life and physiology. Chronic exposure to many metals, however, can result in systemic toxicity. In this chapter, we will discuss clinical manifestation and pathophysiology of poisoning from lead, mercury, arsenic, cadmium, aluminum, cobalt, silver, thallium, zinc, and manganese.

KEYWORDS

lead
mercury

chelation

TABLE 20-2 CHELATORS FOR ADULT HEAVY METAL POISONING

SYMPTOMS	CHELATOR	RECOMMENDED DOSE[†]	ADVERSE EFFECTS
LEAD			
Asymptomatic, BLL[*] < 70 µg/dL	None		
Mild-moderate, BLL 70-100 µg/dL	DMSA	10 mg/kg tid PO × 5 days, then bid for 14 days	Nausea, vomiting, diarrhea, rash, elevations in aminotransferase levels, neutropenia
Encephalopathy, BLL > 100 µg/dL	BAL +	4 mg/kg deep IM q4h × 5 days	Local injection site (pain, redness, sterile abscess); nausea, vomiting, diarrhea; anxiety, hypertension, tachycardia, fever; contraindicated in peanut allergy
	$CaNa_2EDTA$[‡]	1500 mg/m^2/day (approximately 50-75 mg/kg/day, maximum 3 g) either continuous infusion or in 2-4 divided IV doses for 5 days, adjusted for renal insufficiency	Renal toxicity (from metal chelate), constitutional symptoms, transient hypotension
MERCURY			
Acute (elemental or inorganic, but not organic) with moderate/severe symptoms	BAL	5 mg/kg deep IM q4h for 2 days, then 2.5 mg/kg q6h for 2 days, then 2.5 mg/kg bid for 7 days or until symptoms improve and the patient is able to take oral medication, at which point DMSA should be considered	Local injection site (pain, redness, sterile abscess); nausea, vomiting, diarrhea; anxiety, hypertension, tachycardia, fever; contraindicated in peanut allergy
Chronic (elemental or inorganic) or organic with symptoms	DMSA	10 mg/kg tid PO × 5 days, then bid for 14 days	Nausea, vomiting, diarrhea; mild elevations in aminotransferase levels
ARSENIC			
Acute exposure with moderate to severe symptoms	BAL	3 mg/kg deep IM q4h × 2 days, then bid for 7 to 10 days	Local injection site (pain, redness, sterile abscess); nausea, vomiting, diarrhea; anxiety, hypertension, tachycardia, fever; contraindicated in peanut allergy
Chronic exposure with moderate symptoms[§]	DMSA	10 mg/kg tid PO × 5 days, then bid for 14 days	Nausea, vomiting, diarrhea; mild elevations in aminotransferase levels
ALUMINUM			
Acute or chronic exposure in dialysis patient with encephalopathy	Deferoxamine	See *http://kidneyfoundation.cachefly.net/professionals/KDOQI/guidelines_bone/guide12.htm*	Hypotension, increased risk of sepsis, acute lung injury
THALLIUM			
Acute thallium poisoning with moderate to severe symptoms	Prussian Blue	3 g tid PO until the urinary thallium excretion is less than 0.5 mg/day	Constipation, blue stool

*Adult recommendations.
[†]Chelation doses in general are not well studied or validated, with the exception of lead in children. Optimal dosing is not well established, particularly for BAL. Doses listed are author's suggestions.
[‡]Start 4 hours after first dose of BAL is administered.
[§]Benefit in this setting is not established.
BAL = British anti-Lewisite, dimercaprol; bid = twice daily; BLL = blood lead level; DMSA = 2,3-dimercaptosuccinic acid, succimer; EDTA = ethylenediaminetetraacetic acid; h = hour; IM = intramuscularly; IV = intravenously; PO = orally; qd = daily; tid = three times daily.

MERCURY TOXICITY

EPIDEMIOLOGY

Mercury (Hg) is a naturally occurring metal with three distinct forms. Although all forms are neurotoxic, elemental mercury (Hg^0) also causes pulmonary toxicity, inorganic mercury (Hg^+ or Hg^{++}) causes gastrointestinal and renal toxicity, and organic mercury (ethyl, methyl, alkyl, or phenyl) is a teratogen.

Elemental mercury is found in dental amalgams, thermometers, fluorescent lamps, batteries, and some paints. Occupational exposures may occur in dentists and dental hygienists, painters, gold extractors, bronzers, electroplaters, metallurgists, paper pulp manufacturers, miners, ceramic workers, and other workers who use mercury in processing. Mercury thermometers are becoming increasingly rare, and many countries have banned them because of potential mercury toxicity. Toxicity from elemental mercury is caused primarily from breathing its volatilized vapor.

Inorganic mercury has been used historically as a medicinal, cosmetic, and topical antiseptic in the forms of HgCl (calomel) and $HgCl_2$ (mercuric chloride). It is also used in the tanning industry, in taxidermy, in manufacturing of fireworks, and in dye manufacturing. Inorganic mercury may also be found in patent medicines, folk remedies (such as empacho among Mexican Americans), skin lightening creams, and Asian herbal remedies. Toxicity may occur from ingestion, inhalation, or dermal absorption.[8]

Organic mercury compounds can be classified as short-chain alkyl (such as methyl mercury), long-chain alkyl, and aryl compounds. The aryl compounds, such as thimerosal, behave like inorganic mercurial compounds. Methyl mercury has caused several large-scale human poisoning epidemics.

Soil and marine organisms methylate inorganic mercury from the air and industrial waste. Through a process known as bioamplification, methyl mercury concentrates in the tissues of marine life, reaching highest concentrations in large predatory fish such as tuna and swordfish. Fish consumption is now the largest route of organic mercury exposure in the general population, and organic mercury levels have been increasing in the United States even as levels of inorganic mercury have been declining.[9] Organic mercury is also used as a fungicide, pesticide, wood preservative, and medicinal antiseptic or preservative (Mercurochrome and thimerosal). Toxicity is typically by ingestion.

PATHOBIOLOGY

The pathophysiology of mercury poisoning is related to its disruption of cell physiology by binding to sulfhydryl, phosphoryl, carboxyl, and amide groups, thereby causing widespread dysfunction of normal cellular mechanisms. Each type of mercury causes differential effects depending on its route of exposure, solubility, and lipophilicity.

Elemental mercury is poorly absorbed by ingestion. If gastrointestinal motility or mucosal integrity is compromised, however, elemental mercury may ionize into more readily absorbed forms. Elemental mercury toxicity occurs primarily by inhalation of the vapor into the alveoli, where it is well absorbed in the pulmonary circulation and readily crosses the blood-brain barrier. In the brain, it interferes with multiple cellular processes, including protein and nucleic acid synthesis. Mercury also inhibits catechol-*O*-methyltransferase, thereby elevating circulating catecholamine levels.

Inorganic mercury is absorbed after ingestion, initially binds the gastrointestinal mucosa, and accumulates in the kidneys, where it exerts direct oxidative damage. Although it does not readily cross the blood-brain barrier, CNS toxicity can be seen with chronic exposures because of the prolonged elimination rate. Mercuric ions do not appear to cross the placental barrier.

Organic mercury compounds are readily absorbed after ingestion and inhalation and are moderately absorbed after dermal exposure, particularly if skin

is not intact. Owing to its high lipid solubility, organic mercury crosses the blood-brain barrier and concentrates in the CNS. It can also cross the placental barrier and concentrate in the fetus. Organic mercury concentrates in red blood cells, distributes throughout the body, and is primarily eliminated in the feces. Some forms of organic mercury are metabolized in the body to inorganic mercury compounds. Toxicity results from its inhibition of enzyme systems and interference with cellular maturity, microtubule function, and neurotransmitter synthesis and uptake.

CLINICAL MANIFESTATIONS

Elemental Mercury

The manifestations of elemental mercury toxicity vary depending on the dose and chronicity of the exposure. Inhalation of high concentrations of mercury vapor, as may occur in an industrial setting, may result in cough, chills, fever, and shortness of breath. Nausea, vomiting, and weakness may result. This syndrome may progress to a severe acute lung injury and respiratory as well as renal failure. Chronic exposure to lower concentrations of mercury vapor produces a classic triad of tremor, gingivostomatitis, and neuropsychiatric disturbances. The mercurial tremor may be both static and intentional. Sudden episodic bursts of tremor, also called tetanus mercurialis, have been described. Neuropsychiatric manifestations of mercury poisoning, also known as erethism, include fatigue, insomnia, memory dysfunction, social withdrawal, shyness, and depression. Acrodynia, or pink disease, has been described after elemental or inorganic mercury exposure, most notably in children after exposure to mercurial teething powder and diaper ointment. This syndrome is manifested as an erythematous, hyperkeratotic, often desquamating rash on the palms, soles, and face in conjunction with a papular rash. Acrodynia is also associated with an idiosyncratic hypersensitivity to mercury ions and mercury poisoning, which itself can increase circulating catecholamines and mimic pheochromocytoma (Chapter 209). Common findings include tremor, diaphoresis, tachycardia, and hypertension.

Inorganic Mercury

Inorganic mercury poisoning can occur after dermal or mucosal absorption of mercury-containing cosmetics and teething powders as well as after accidental or intentional ingestion of mercuric chloride antiseptics. After acute ingestion, a hemorrhagic gastroenteritis is typically followed by renal failure from acute tubular necrosis. Chronic exposure is associated with erethism, renal dysfunction, and neurologic manifestations such as sensorimotor neuropathy, constriction of visual fields, tremor, and delirium.

Organic Mercury

Human toxicity from organic mercury was first recognized when the dumping of mercury-containing waste into Minamata Bay in Japan led to a large-scale poisoning of the population, whose primary dietary staple was fish from the bay. In what is now called Minamata disease, patients presented with paresthesia, ataxia, dysarthria, tremor, and constriction of visual fields or "tunnel vision."[10] These symptoms can be progressive and sometimes fatal. Children born to these exposed mothers (congenital Minamata disease) suffered mental retardation, limb deformities, chorea, seizures, and microcephaly. In a large Korean study, higher mercury levels were associated with depression in women but not men, and even then only in women with low fish consumption.[11] In the United States, organic mercury exposure from seafood has not been significantly associated with cardiovascular or all-cause mortality.[12] Nevertheless, higher circulatory levels of mercury (along with aluminum and cadmium) are found in patients with Alzheimer disease than in controls.

With organic mercury toxicity, symptoms are typically delayed for weeks to months. Other symptoms that follow organic mercury poisoning include mucous membrane irritation after ingestion and dermatitis after cutaneous exposure. However, no cardiovascular toxicities have been reported with up to moderate elevation in blood mercury levels.

DIAGNOSIS

The diagnosis of mercury poisoning should be considered on recognition of the characteristic signs and symptoms coupled with a known or suspected exposure. Whole blood and urine mercury levels can confirm the exposure, but the correlation between levels and symptoms is inconsistent. In the setting of elemental mercury ingestion or injection, radiographs may also be useful. In a nonoccupationally exposed patient, whole blood mercury concentration should not exceed 10 μg/L, and a 24-hour urine mercury concentration should not exceed 20 μg/L (Table 20-1); urine must be collected in an acid-washed container. In general, urine concentrations are more reliable for monitoring of exposure and the response to therapy, but whole blood concentration is the preferred monitoring test for methyl mercury poisoning.

The ratio of red blood cells to plasma mercury can differentiate organic mercury toxicity from inorganic mercury toxicity because organic mercury concentrates significantly in red blood cells. Hair analysis is unreliable because of the potential for external contamination. The practice of obtaining urine mercury levels after a chelation challenge is not recommended because levels obtained in this way are difficult to interpret.

TREATMENT

Treatment is primarily symptomatic and supportive, with removal from the source of exposure. In cases of acute exposure, decontamination may be required. In cases of occupational or environmental exposure, environmental decontamination and surveillance by local or federal agencies may be necessary. After inhalation of elemental mercury vapor, support of respiratory function is crucial. After ingestion of inorganic mercury salts, fluid resuscitation, usually with normal saline, is needed to correct intravascular depletion, and renal replacement therapy may be required in cases of oliguric renal failure. Mercury compounds are poorly cleared by extracorporeal elimination measures, such as hemodialysis or peritoneal dialysis.

If dietary fish is the likely cause of an elevated mercury level, affected individuals should avoid eating any fish or shellfish for 1 month, after which blood or urine mercury levels should be reanalyzed. If mercury levels have declined into the normal range, as is usually the case, low-mercury fish (shrimp, canned light tuna, salmon, pollock, catfish) can be reintroduced into the diet at a frequency of no more than two meals per week.

Chelation therapy will increase urinary elimination of mercury (Table 20-2), and limited clinical data support its use early after acute poisonings. Oral DMSA, which is the chelator of choice, is generally well tolerated. If oral administration is not possible, dimercaprol (British anti-Lewisite, BAL) can be used except after methyl mercury exposure, in which it is contraindicated because it may shift mercury into the brain.

PROGNOSIS

The neurotoxicity that follows significant poisoning from all types of mercury may be irreversible, particularly in the setting of organic mercury poisoning, in which the diagnosis is often delayed. Nevertheless, 33 of 40 symptomatic children affected in the contaminated grain outbreak of 1971 in Iraq improved during a 2-year observation period. Acute renal failure after elemental or inorganic mercury poisoning can sometimes resolve. Patients with acrodynia have been reported to recover completely after chelation therapy and removal of the exposure.

ARSENIC TOXICITY

EPIDEMIOLOGY

Arsenic (As), which is found in soil, minerals, rocks, and metal ores, is present in all living organisms. It exists in several forms: elemental, inorganic (As^{3+} trivalent arsenite and As^{5+} pentavalent arsenate), gaseous (arsine, AsH^3), and organic. Elemental and organic arsenic have low toxicity, whereas gaseous arsine and inorganic arsenic are highly toxic. Arsenic's medicinal properties were recognized as early as 400 BC, and it has been used throughout history as a medicinal as well as a component of pigments, cosmetics, and famously as a poison.

Human exposure to arsenic may occur through contaminated air, groundwater, soil, and food, particularly seafood, rice, and produce.[13] Marine organisms, especially shellfish, contain organic arsenicals arsenobetaine and arsenocholine, which are commonly reported in laboratory assays as elevated arsenic level but exert no known toxic effects.

In Bangladesh, ongoing epidemic arsenic poisoning from contaminated groundwater has affected millions of persons. Taiwan, Chile, the Cordoba province in Argentina, West Bengal, and other regions in the Ganga plain also have elevated levels of naturally occurring arsenic and cases of arsenic poisoning.

Occupational exposure to arsenic occurs in the microelectronics industry, where arsenide crystals are used to etch circuits on microchips. Arsine gas is liberated when inorganic arsenic contacts acid, as may occur in occupations such as metal smelting, galvanizing, and semiconductor manufacturing. Arsenic compounds are also used in the production of paint, fungicide, insecticide, pesticide, herbicide, wood preservatives, ceramics, and glass, and employees in these industries may also be potentially exposed.

Arsenic compounds may still be found in folk remedies and patent medicines. Modern medicinal uses of arsenic include arsenic trioxide (Trisenox) for the treatment of acute promyelocytic leukemia and other hematologic

malignancies (Chapter 168), and melarsoprol (which is not commercially available in the United States), for the treatment of African trypanosomiasis (Chapter 317).

PATHOBIOLOGY

The toxicologically significant arsenic compounds are inorganic (trivalent and pentavalent). Arsine gas, which is also toxic, causes acute hemolysis. After absorption, inorganic arsenic binds to hemoglobin and is distributed to the liver, kidney, heart, and lungs. In the liver, arsenic is methylated to form monomethylarsonic and dimethylarsinic acid, both of which are less toxic. Arsenic concentrates in keratin-rich tissues, such as hair, skin, and nails. Much of an ingested dose of arsenic is eliminated in the urine. The mechanism of toxicity is by binding sulfhydryl groups of critical enzymes, including those of the Krebs cycle, thereby resulting in impaired gluconeogenesis, impaired oxidative phosphorylation, and ultimately depletion of cellular energy stores. DNA damage and an impaired DNA repair mechanism contribute to carcinogenic effects. Pentavalent arsenate may substitute for phosphate in biochemical reactions and disrupt normal oxidative phosphorylation. Arsenic also affects cardiac conduction by blocking cardiac potassium channels. Arsenic can alter gene expression through induction, downregulation, and upregulation of various genes involved in apoptosis, cell signaling, and growth factor response.

Arsine is a colorless, nonirritating gas. After inhalation, it is absorbed rapidly and binds to erythrocytes, where it exerts oxidative stress and causes severe Coombs-negative intravascular hemolysis. Renal failure is due to hemoglobin pigment deposition as well as to the direct toxic effects of arsine on renal tubular cells.

CLINICAL MANIFESTATIONS

The initial clinical features after acute ingestion of inorganic arsenic are nausea, vomiting, bloody diarrhea, and abdominal pain. Severe manifestations such as seizures, delirium, and coma are seen after large exposures. Within several days, hematologic findings such as pancytopenia can be seen. QT prolongation, which can develop acutely or chronically, can lead to dysrhythmias such as torsades de pointes. After gastrointestinal symptoms improve, distal symmetrical peripheral neuropathy develops, potentially accompanied by weakness or encephalopathy.

Chronic exposures affect the bone marrow, skin, and peripheral nervous system.[14] Dermatologic effects include patchy or diffuse alopecia, hyperpigmentation, and melanosis as well as hyperkeratosis on the palms and soles. The pigmentation of chronic poisoning commonly appears in a finely freckled, "raindrop" pattern of symmetrical pigmentation or depigmentation that is particularly pronounced on the trunk and extremities. Nails may exhibit transverse white bands, which are known as Mees lines (Chapter 409) and reflect growth interruption during poisoning. Anemia, pancytopenia, neutropenia, thrombocytopenia, and eosinophilia can be seen. Neuropathy, which is a hallmark of arsenic poisoning, is a diffuse, symmetrical, ascending, painful sensorimotor neuropathy, most prominent in a stocking-glove distribution. In severe poisoning, ascending weakness and paralysis may result in respiratory failure that mimics Guillain-Barré syndrome (Chapter 388). Arsenic exposure also causes a dose-dependent decline in lung function.[15] Peripheral vascular disease, including peripheral vascular gangrene (black foot disease), can develop in chronically exposed patients. Even low to moderate chronic arsenic exposure increases the long-term risk of cardiovascular disease. Arsenic is a human carcinogen, and exposed populations have an increased risk of developing malignant neoplasms in the lung, skin, and bladder.[16]

Arsine gas produces a clinical triad of abdominal pain, hemolysis, and hematuria, typically occurring hours after exposure. Patients may initially have headache, weakness, nausea, and vomiting. Several weeks after an acute exposure, peripheral neuropathy may develop.

DIAGNOSIS

Blood arsenic, urine arsenic, and urine arsenic metabolites can be used to confirm recent or ongoing exposure. In the unexposed individual, blood arsenic should be below 1 μg/L; hair and nail levels should be less than 1 ppm.[17]

However, arsenic clears from the blood quickly, so urine levels are most helpful to diagnose chronic or past exposure. Arsenic levels above 50 μg in a spot urine test warrant a 24-hour test. Urine is collected in a metal-free polyethylene container, and levels exceeding 50 μg or 100 μg/g creatinine in a 24-hour collection require further scrutiny (Table 20-1). Patients who have recently ingested seafood may have urine arsenic levels exceeding 1500 μg/L exclusively from organic arsenic, so differentiating inorganic from nontoxic organic arsenic is often critical. Total arsenic levels in hair or nails, where arsenic accumulates, are useful indicators of past exposures.

In patients with chronic arsenic exposure, a complete blood count may show anemia (normocytic, normochromic, or megaloblastic), leukopenia, and thrombocytopenia. A peripheral smear may show basophilic stippling (see Fig. 143-14) or karyorrhexis. Renal dysfunction, hepatic enzyme elevation, and hyperbilirubinemia may be seen as well. The electrocardiogram may show QT prolongation and nonspecific ST-T wave changes. Nerve conduction studies typically show evidence of a distal symmetrical sensorimotor axonopathy. Conduction slowing may be seen in severe poisoning.

TREATMENT

Initial treatment of arsenic toxicity includes supportive care, fluid repletion, decontamination if needed, and removal of the source of exposure. Hemodialysis may be required in patients who have significant renal dysfunction.

In cases of severe acute poisoning from inorganic arsenic, chelation is beneficial if it is instituted early. Dimercaprol (BAL; see Table 20-2), which is the traditional chelating agent for arsenic, is effective in decreasing morbidity and mortality if it is administered within minutes to hours of acute exposure. The oral analogue of BAL, dimercaptosuccinic acid (DMSA, succimer) is also useful for subacute or chronic arsenic poisoning. 2,3-dimercapto-1-propanesulfonic acid (DMPS) has also been used successfully but is neither approved by the Food and Drug Administration nor commercially available in the United States. In chronic inorganic arsenic intoxication, however, a clear benefit of chelation therapy has not been demonstrated.

Hemolysis caused by arsine gas poisoning should be treated with prompt exchange transfusion. Exchange transfusion can restore functional erythrocytes, remove hemoglobin pigments, remove arsenic itself, and remove toxic products formed in the arsine-hemoglobin reaction.

PROGNOSIS

Outcomes after arsenic poisoning are influenced by the dose, type of arsenic compound, and route and chronicity of exposure. Acute high-dose arsine gas inhalation with severe and rapid systemic toxicity can be fatal. With appropriate treatment, however, recovery has been reported. After acute inorganic arsenic ingestion, rapid diagnosis and treatment, including chelation, can significantly reduce mortality. After acute or chronic arsenic poisoning, electrocardiographic abnormalities and bone marrow suppression are generally reversible after exposure ceases, but encephalopathy and neuropathy may be permanent. Skin changes, such as hyperpigmentation and hyperkeratoses, can progress to cancer but also can improve with mitigation of exposure.

CADMIUM TOXICITY

EPIDEMIOLOGY

Cadmium (Cd) is primarily found in zinc ores as cadmium sulfide. Serious human exposures usually come from industrial use, including the production of nickel-cadmium batteries, electroplating, soldering, and welding. Workplace exposures occur through inhalation of dust containing oxides of cadmium or fumes from welding or smelting of metals containing cadmium.[18] Depending on the particle size, more than 50% of cadmium can be absorbed through the lungs, but little cadmium is absorbed through the gastrointestinal tract. Many plants take up cadmium from the environment, but poor oral bioavailability and relatively low food concentrations make ingestion of food an unlikely source of significant cadmium. An exception is when cadmium-containing industrial waste is dumped in agricultural regions, such as happened in Japan in the 1950s, when cadmium-containing mining waste in waterways that irrigated rice fields caused a large outbreak of osteomalacia, painful fractures, and renal disease ("itai-itai", or ouch-ouch syndrome). Today, a common source of environmental cadmium exposure is through smoking, because tobacco concentrates cadmium from the soil. Compared with nonsmokers, an average smoker has twice the concentration of total body cadmium.

PATHOBIOLOGY

Cadmium commonly exists as a divalent ion (Cd^{2+}) in salts such as cadmium sulfide and cadmium oxide. As with other divalent metals, it binds to and inhibits sulfhydryl-containing proteins and enzymes, thereby resulting in oxidative stress, cellular apoptosis, or necrosis. To survive in an environment where metals are ubiquitous, mammals have developed numerous antioxidant systems for protection. The one best studied in cadmium is the protein metallothionein, which is an intracellular, cysteine-rich protein especially found in the liver and kidney, where it is a potent protective antioxidant that binds to ionized

cadmium.[19] Slow release of cadmium from the cadmium-metallothionein complex results in a long biologic half-life of over 20 years.

CLINICAL MANIFESTATIONS

The most life-threatening manifestation of cadmium toxicity is acute chemical pneumonitis (Chapters 81 and 82). In persons who are exposed to high concentrations of cadmium fumes (e.g., smelter or welders), cadmium pneumonitis is manifested like metal fume fever with fever, malaise, myalgias, and elevated white blood cell counts that develop within 12 hours of exposure. Unlike metal fume fever, which typically resolves within a few days, cadmium pneumonitis can progress, with symptoms of dyspnea, hemoptysis, pulmonary edema, and respiratory distress, as well as diffuse bilateral alveolar infiltrates on the chest radiograph.

The most problematic manifestation of chronic cadmium exposure is renal failure. As with lead, cadmium can damage the proximal tubules of the kidney and result in Fanconi syndrome (Chapter 113). Cadmium, bound to metallothionein, accumulates in the kidney; once metallothionein binding is saturated, toxicity can develop. Unlike the acute pulmonary manifestations, renal symptoms of cadmium toxicity may have a latency of decades. Clinically, the signs of renal disease from cadmium are not different from those of other causes of proximal tubular disease, with proteinuria being the most common finding. Patients will often manifest secondary symptoms of renal dysfunction, such as osteoporosis, osteomalacia, or ureteral stones owing to impaired calcium metabolism. Hypertension and anemia from cadmium exposure are also likely secondary to its renal toxicity.

DIAGNOSIS

No laboratory tests can aid in the diagnosis of cadmium pneumonitis, so physicians must rely on their clinical suspicion or on alveolar infiltrates on a chest radiograph in a cadmium-exposed worker who presents with influenza-like symptoms. Patients may present with an initially benign clinical picture and progress to respiratory failure.

Diagnosis of renal toxicity from chronic cadmium exposure relies predominantly on a 24-hour urine cadmium level standardized to grams of creatinine in a certified laboratory experienced in heavy metal testing (Table 20-1). In nonexposed nonsmokers, cadmium values should average about 0.08 μg/g creatinine. For patients with levels above 3 μg cadmium/g creatinine, a medical evaluation and renal testing are indicated. Levels at or above 7 μg cadmium/g creatinine require removal from the workplace. Urinary β_2-microglobulin levels increase as proximal tubular function worsens and can serve as a useful early marker of toxicity; levels above 300 μg/g creatinine should raise concern for early kidney disease.

TREATMENT

Because of the progression of potentially life-threatening pulmonary symptoms in cadmium pneumonitis, any patient presenting with influenza-like symptoms after working with heated cadmium should be admitted for observation. If the metal a patient was welding or cutting is not known, any clinical or radiographic signs of noncardiogenic pulmonary edema would also warrant hospital admission for supplemental oxygen and pulmonary support.

There are no effective specific treatments for acute or chronic cadmium toxicity. Chelation therapy is not recommended. Cessation of exposure is recommended but is not likely to reverse renal or pulmonary damage.

PROGNOSIS

Patients with cadmium pneumonitis can survive with aggressive supportive treatment, but severe cases can result in death, and survivors can have persistent restrictive lung disease. Because of its long half-life in the kidney, cadmium-induced renal damage is largely irreversible unless it is detected early when body burden is low (urinary cadmium < 10 μg/g creatinine).

SYNDROMES SPECIFIC TO OTHER TOXIC METALS

ALUMINUM (DIALYSIS DEMENTIA)

In the 1970s, patients who had renal failure and who were exposed to aluminum-containing phosphate binders or aluminum-contaminated dialysis fluid developed progressive neurologic impairment and seizures. Also known as dialysis dementia, this syndrome developed during weeks to years and was often fatal if undetected. Aluminum-containing phosphate binders and dialysis fluids are no longer used in patients with renal failure, and at-risk dialysis patients are screened for aluminum toxicity. As a result, this phenomenon has decreased over time,[20] but occasional outbreaks continue to be reported, typically owing to contamination of dialysis fluid with aluminum from electric pumps or drums.

Aluminum is found in air, soil, and water and is a component of metal alloys used in the home, such as cookware. Aluminum is also found in some antacids (sucralfate) and as aluminum potassium sulfate (Alum), which is used to treat hemorrhagic cystitis. Additional iatrogenic sources of aluminum include total parenteral nutrition solutions and vaccines. Ingested aluminum is not metabolized by the body and is excreted unchanged by the kidney. In patients who have impaired renal function, aluminum is bound to transferrin and concentrates primarily in bone. Smaller amounts, however, are distributed to the heart, liver, kidney, and brain. Ingested aluminum is thought to affect several biochemical functions, including neurotransmitter manufacture, uptake, and release. Aluminum also affects erythropoiesis and the normal function of bone, likely partially by interference with parathyroid function.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Clinical effects in patients with chronic exposures include anemia, osteomalacia, and neurologic effects including memory loss, tremor, dyspraxia, encephalopathy, and seizures.[21] A relationship between aluminum and Alzheimer dementia has been proposed, but the complex characteristics of aluminum bioavailability make it difficult to produce conclusive evidence.

Serum and urine aluminum levels can be obtained to estimate exposure. A serum aluminum concentration should not exceed 2 μg/L, and a 24-hour urine concentration is expected to be 4 to 12 μg per gram of creatinine in a patient with typical background aluminum exposure (Table 20-1).

TREATMENT AND PROGNOSIS

Management of aluminum toxicity centers on removal of the source of exposure. The only chelator with proven benefit is deferoxamine (Table 20-2), which has a high affinity for aluminum and forms a dialyzable aluminum-deferoxamine complex. If neurologic dysfunction is detected early, successful treatment and full recovery have been reported with deferoxamine.

BISMUTH (BISMUTH ENCEPHALOPATHY)

Bismuth salts used to treat gastrointestinal disorders include bismuth subgallate, bismuth citrate, bismuth subnitrate, and bismuth subsalicylate (the active ingredient in Pepto-Bismol). Bismuth (Bi) is poorly absorbed from the gastrointestinal tract and is still used today to treat peptic ulcer disease and diarrhea. It also is used as an oral deodorant for patients with colostomies. Idiopathic bismuth toxicity is almost always associated with the chronic ingestion of over-the-counter preparations.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Bismuth toxicity is manifested primarily as a subacute encephalopathy with ataxia and incoordination followed by progressive memory loss, behavioral changes, insomnia, and muscle cramps. As symptoms progress, a common feature is limb myoclonus when patients are startled or as they fall asleep. As symptoms worsen, myoclonus can progress to involve the entire body, including the tongue, and can occur without stimulus. Seizures can also develop.

The diagnosis of bismuth encephalopathy can be difficult. Blood and urine levels can indicate exposure to bismuth (Table 20-1) but do not correlate with symptoms. Furthermore, electroencephalographic findings, laboratory tests, and imaging studies are not specific. Because of its similarity in onset and symptoms, bismuth encephalopathy is often misdiagnosed as Creutzfeldt-Jakob disease (Chapter 371) or other progressive encephalopathies. Therefore, any patient in whom these diagnoses are being entertained should be screened for the use of bismuth products. Because bismuth causes black stools, the finding of heme-negative black stool in a patient with a rapidly progressing encephalopathy warrants an investigation for bismuth toxicity.

TREATMENT AND PROGNOSIS

The treatment of bismuth encephalopathy is to stop the use of the offending agent. Although case reports have reported benefits with metal chelators (e.g., DMSA, BAL, and 2,3-dimercapto-1-propanesulfonic acid; see Table 20-2), the rarity of the disorder makes a clinical trial impossible. Ethylenediaminetetraacetic acid (EDTA) may increase brain bismuth concentrations, so it should not be used. Although deaths have occurred from bismuth encephalopathy, full recovery is possible if the offending drug is stopped and if the patient receives modern supportive care.

COBALT (THYROID AND CARDIAC TOXICITY)

Cobalt (Co) is an essential trace element that serves as the catalytic center of vitamin B_{12}. Toxicity is associated with chronic ingestion of cobalt salts and more recently from cobalt-containing metal prostheses. One of the side effects of chronic ingestion is polycythemia (Chapter 152). By stabilizing hypoxia-inducible transcription factors that normally respond to low concentrations of oxygen, cobalt mimics hypoxia and stimulates erythropoietin production. In the 1950s, cobalt chloride was used to treat iron deficiency anemia. Some of these patients developed hypothyroidism and goiter because of cobalt's ability to inhibit tyrosine iodinase. In addition, cobalt has caused dilated cardiomyopathy with pericardial effusions in adults who consumed large amounts of beer in which cobalt salts had been added as a foam stabilizer. Cobalt can cause neurotoxicity with symptoms of hearing loss, visual impairment, and polyneuropathy.

Current concern for cobalt toxicity is predominately for patients who have cobalt-chromium prosthetic joints. Cobalt liberated from a prosthesis has been linked to hypothyroidism (Chapter 207), dilated cardiomyopathy (Chapter 47), and neurotoxicity with metal-on-ceramics arthroplasty and metal-on-metal prosthetics.

DIAGNOSIS AND TREATMENT

The diagnosis in a patient with a cobalt-containing joint replacement requires symptoms of polycythemia, hypothyroidism, cardiomyopathy, and neurotoxicity. In these patients, a blood chromium level above 7 μg/L should stimulate a referral for a possible joint revision.

There is little evidence that chelation improves outcomes in cobalt-poisoned patients.

SILVER (ARGYRIA)

Silver (Ag) is a precious metal long used in coinage and for its antibacterial properties. Silver is a broad-spectrum antimicrobial and commonly used as a topical antimicrobial in bandages, catheters, and medical devices. The ingestion of colloidal silver preparations as a "natural" supplement accounts for the majority of recent cases of significant toxicity.

When it is ingested continually, silver will be deposited in the skin and the liver.[22] The primary chronic toxicity of silver is argyria, which is a permanent blue-gray discoloration of the skin owing to silver deposition over time (Fig. 20-1). Argyria can result from inhalation, ingestion, mucosal absorption, or dermal application or exposure. Argyria may be localized to the site of exposure, such as with corneal argyria, which was seen in the past from the use of colloidal silver–containing eye drops, or at the site of silver earrings and rings. Rarely, argyria has been reported after the implantation of silver-containing medical devices.

DIAGNOSIS AND TREATMENT

The diagnosis of argyria is primarily based on history and physical examination. Localized skin biopsy, typically to differentiate argyria from malignant lesions, will show characteristic black-brown globules that are adherent to the dermal elastic fibers, blood vessels, basement membranes, hair follicles, and sweat glands on light microscopy; refractile particles on darkfield microscopy; and the presence of silver on scanning electron microscopy with energy dispersive radiography.

Chelation therapy is not effective for argyria, but successful laser treatment has been reported.[23]

THALLIUM (NEUROPATHY AND ALOPECIA)

Thallium (Tl) has no beneficial role in the human body. Its salts are odorless, tasteless, well absorbed in the gastrointestinal tract, and very toxic. These characteristics make it a potential homicidal agent, and patients with thallium poisoning should always be considered potential victims of a crime. By interfering with potassium and sulfhydryl-containing enzymes, thallium interrupts normal energy production. Although it is toxic to all organs, the peripheral nervous system and integumentary system are the most sensitive.

The earliest clinical sign of thallium poisoning is a rapidly progressive, painful sensory polyneuropathy. Within 2 or 3 days of exposure, patients will describe painful burning paresthesias in their feet. These paresthesias can progress up the legs and, over time, can involve the hands. Motor nerves can also be affected, and profound weakness, including in respiratory muscles, can be misdiagnosed as Guillain-Barré syndrome (Chapter 388). Cranial neuropathies have also been reported. Thallium toxicity causes painless hair loss, typically beginning 5 to 14 days after exposure and sometimes progressing to total body alopecia. Skin and nails can also be affected, with scaling of palms, acne-like lesions of the face, and Mees lines in the nails. Other neurologic symptoms of thallium poisoning include hallucinations, altered mental status, insomnia, psychosis, ataxia, and coma. Constipation, myalgias, pleuritic chest pain, arrhythmias, and hypotension can also occur.

Systemic toxicities often develop before hair loss and because not all patients lose their hair, clinicians should consider thallium as a possible cause of any rapidly progressive painful neuropathy. In patients with thallium poisoning, a pulled hair will often have darkening of the hair root when visualized under a low-power light microscope.

FIGURE 20-1. Frontal and side views of a 36-year-old woman with argyria show the gray discoloration of her face and neck. (From Jacobs R. "Argyria: my life story," *Clin Dermatol*. Elsevier, 2006;24:66-69. Figure 3.)

DIAGNOSIS AND TREATMENT

The diagnosis of thallium poisoning requires the identification of elevated concentrations of thallium in a 24-hour urine sample (normal, <20 μg/specimen). Because thallium undergoes enterohepatic circulation and is eliminated in the feces, treatment requires binding of thallium in the gut. The most effective antidote is Prussian blue (a complex of potassium hexacyanoferrate), with recommended doses ranging from 3 g orally three times a day up to 250 mg/kg three times a day. Patients with thallium toxicity have received plasma exchange and continuous renal replacement therapy, but the benefit of these therapies is unknown.[24]

ZINC (MYELOPATHY)

Zinc (Zn) is an essential mineral that is necessary for normal cellular functioning. It is involved in the catalytic activity of more than 200 enzymes and plays an important role in olfaction, taste, immune function, protein synthesis, and DNA synthesis. It is found naturally in a wide variety of foods and is absorbed in the jejunum, where it binds to metallothioneins. Patients at risk for zinc deficiency include those with intestinal bypass, Crohn disease, and patients receiving total parenteral nutrition without adequate zinc supplementation. Zinc deficiency is manifested as a triad of dermatitis, diarrhea, and alopecia, which is reversible after zinc repletion.

In the setting of zinc overload, metallothioneins are upregulated; because copper has a higher affinity for metallothioneins, the result is increased copper binding and subsequent elimination of copper. Zinc-induced copper deficiency has been reported after overuse of zinc-containing supplements, with the improper use of zinc-containing denture adhesives, and from the presence of retained zinc-containing coins such as pennies.

The hematologic manifestations of zinc-induced copper deficiency include sideroblastic anemia, leukopenia, neutropenia, and myelodysplastic syndrome, all of which are reversible with zinc cessation alone. In addition, a syndrome of myeloneuropathy,[25] characterized by a spastic gait and sensory ataxia, is also associated with zinc overload/copper deficiency and may improve with copper supplementation and zinc cessation.[26]

Diagnostic testing in patients suspected of zinc overload should include serum or urine zinc concentrations (Table 20-1), serum copper levels, and ceruloplasmin levels. In patients with myeloneuropathy, nerve conduction studies may show a sensory neuropathy, and MRI may show increased T2 signal in the dorsal columns of the cervical spinal cord.

TREATMENT

Treatment of zinc overload–induced copper deficiency is primarily by cessation of zinc exposure and repletion of copper. Although there is no standard dosing regimen, a common recommendation is 2 to 8 mg/day of oral elemental copper. Various chelation regimens have been reported, but data are insufficient to support their routine use in the setting of chronic toxicity.

MANGANESE (PARKINSONISM)

Manganese (Mn) is an essential element necessary for the function of several enzymes, including superoxide dismutase and glutamine synthetase. Although there is no clear syndrome associated with manganese deficiency, a well-described constellation of symptoms and findings is associated with manganese toxicity. Dose-dependent manganese toxicity, primarily with chronic occupational exposure, results from inhalation of high concentrations of either manganese dust (e.g., in miners) or manganese fumes (e.g., smelting, grinding, and rarely welding). Toxicity has also been reported with overuse of supplements or use of illicit methcathinone synthesized with potassium permanganate.

The mechanism of neurotoxicity from manganese exposure is likely multifactorial, including neuroinflammation, dysregulation of mitochondrial function and cell signaling, oxidative stress, altered metabolism of neurotransmitters, and alterations in manganese transporters and homeostasis.[27] Manganese causes selective toxicity in the globus pallidus, striatum, and substantia nigra pars reticulata.

CLINICAL MANIFESTATIONS

The symptoms of manganism develop insidiously after years of exposure. Patients first develop changes in appetite, muscle weakness, and apathy. On occasion, patients will develop signs of central excitation and can have what is termed manganese psychosis. Symptoms often progress to difficulties with gait, speech, and facial expression.[28] The gait abnormalities involve a slow and clumsy gait with the inability to walk backward. Patients often freeze while turning and frequently fall. Symptoms can progress to muscle hypertonia in extension and a peculiar gait in which patients walk on the balls of the feet with their ankles extended. Patients also develop stuttering speech, masked facies, sleep disturbances, and myalgias. Unlike with idiopathic Parkinson disease (Chapter 378), patients with manganism do not typically develop a resting tremor or resting dementia, and their symptoms do not typically respond to levodopa therapy.[29]

DIAGNOSIS

Although there is no definitive test of manganese toxicity, a history of exposure, confirmatory laboratory testing (Table 20-1), radiographic studies, and clinical symptoms can support the diagnosis. The best laboratory test is a whole blood manganese level (normal, <15 μg/L), with elevated levels indicative of exposure but not necessarily correlating directly with symptoms. Because manganese can concentrate in the globus pallidus, MRI often will show an intense T1-weighted signal in the globus pallidus bilaterally. However, MRI is indicative of manganese exposure but does not correlate with clinical symptoms. Because of the differences in the affected brain regions between manganese toxicity and Parkinson disease, fluorodopa positron emission tomography (PET) scanning can help differentiate between these disorders: patients with manganese toxicity will typically have normal PET scans, whereas patients with Parkinson disease have abnormal scans.

TREATMENT

Manganism is not typically responsive to treatment, but removal from exposure is important. Although chelation with $CaNa_2EDTA$ has been associated with increased urinary elimination of manganese, patient outcomes would not be expected to improve with chelation.

Adolescence, a period of transition between childhood and adulthood, is marked by critical biologic, psychological, social, and cognitive changes. During this unique developmental period, patterns of behaviors and lifestyle choices are established that can influence current and future health, and unique medical and psychological problems can emerge. Adult-oriented health care providers play a pivotal role in engaging youth in their health and in providing health care to adolescents.

NORMAL PHYSICAL GROWTH AND DEVELOPMENT

Biologic growth and development in adolescents are signified by the onset of puberty (Chapter 217), which varies temporally among adolescents and explains why adolescents of the same chronologic age can vary greatly in physical appearance. The first visible sign of puberty among girls is usually thelarche, or the development of breast buds, which occurs on average at 10 years in White girls and 1 year earlier in African American girls (Chapter 217).

Menarche occurs 2 to 4 years after the initial appearance of breast buds and pubic hair. The average age of menarche is 12.9 years for White American girls and 12.2 years for African American girls. Menstrual periods are not always regular during the first 2 years after menarche. At menarche, only 20% of cycles are ovulatory; it may take up to another 4 years for 80% of cycles to be ovulatory. The average time for completion of puberty in girls is 4 years (range, 1.5 to 8.0 years).

Puberty begins about 1 year later in boys than in girls. The first physical signs of puberty in boys, testicular enlargement and thinning of the scrotum, occur at 10 years. Adrenarche usually begins about 6 months later (Chapter 216), and facial hair appears about 3 years after the appearance of pubic hair. The completion of puberty in boys averages 3 years (range, 2 to 5 years).

Pubertal weight gain accounts for about half of a person's ideal adult body weight. Peak weight gain follows the linear growth spurt by 3 to 6 months in adolescent girls and by about 3 months in adolescent boys. The average weight gain during puberty among adolescent girls is 15 to 55 lb or 7 to 25 kg (mean gain, 38.5 lb or 17.5 kg). Overall, adolescent boys gain 15 to 65 lb or 7 to 30 kg during puberty (mean gain, 52.2 lb or 23.7 kg).

Boys' body fat levels decrease during adolescence, dropping to 12% body fat by the end of puberty. On average, adolescent girls' lean body mass falls from 80 to 75%, whereas their average body fat levels increase from 16 to 27% by the end of adolescence. By the time adolescent girls are 16 years of age and adolescent boys are 18 years of age, they have accrued more than 90% of their adult skeletal mass.

Sexual maturity ratings (SMRs), also known as Tanner stages, are used to describe the progression of secondary sexual characteristics that occur in adolescents, irrespective of chronologic age. SMR is based on the development of breasts and the appearance of pubic hair among girls (E-Fig. 21-1) and on testicular and penile development and the appearance of pubic hair among boys (E-Fig. 21-2). SMR 1 corresponds to the prepubertal stage: puberty has not begun and no sexual development has occurred. SMR 2 to SMR 5 indicates the progression of puberty to adulthood. Once young people reach SMR 5, they have fully developed secondary sexual characteristics. Sexual maturation correlates with linear growth, changes in weight and body composition, and hormonal changes.[1] Sexual maturation provides important assurance of the normal progression of puberty or identification of abnormal pubertal development.

NORMAL PSYCHOSOCIAL DEVELOPMENT

Adolescence is often divided into three psychosocial developmental phases: early adolescence (11 to 13 years), middle adolescence (14 to 16 years), and late adolescence (17 to 21 years). In early adolescence, adolescents begin to separate from their parents and establish an individual identity. As adolescents pull away from parents in search of their own identity, their peer group begins to take on increasing salience.

At the beginning of adolescence, cognitive abilities are dominated by concrete thinking. Young adolescents lack abstract reasoning capabilities, problem-solving skills needed to overcome barriers to behavioral changes, and the ability to appreciate how current behaviors can affect future health status.

Middle adolescence is characterized by growth in emotional autonomy and increasing separation from family. The adolescents' peer groups play a powerful role, and adolescents are increasingly involved in partnering relationships that include dating, sexual experimentation, and adverse health behaviors such as smoking cigarettes, drinking alcohol, using street drugs, and being truant. Abstract reasoning skills emerge but often regress to concrete thinking when adolescents are faced with stressful situations. These adolescents begin to understand the relationship between health behaviors and future health status, but peer pressure may make it challenging for them to make appropriate health-related choices.

During late adolescence, young people become increasingly more emotionally independent. Peer group values become less important, and young people spend more time in a relationship with one person. This late stage of adolescence is characterized by the development of a strong personal identity. Abstract reasoning skills expand, and older adolescents have problem-solving skills that help them overcome challenges to behavioral change.

VITAL STATISTICS

Morbidity and mortality among 10- to 19-year-olds are often the result of risky behaviors and environmental factors (Table 21-1).[2] Unintentional injury is the leading cause of death in this age group. Malignant neoplasms, suicide, and homicide are the next three leading causes. Most deaths due to intentional injury (i.e., suicide and homicide) are theoretically preventable.

UNINTENTIONAL AND INTENTIONAL INJURIES

Unintentional injuries account for 25 to 35% of all deaths among 10- to 19-year-olds. Major causes of unintentional injuries include motor vehicle accidents, drowning, fire, poisoning, and falls. Factors that contribute to adolescent injuries include socioeconomic factors (adolescents from low-income families are at greatest risk for injury), environmental factors (hazards such as all-terrain vehicles, backyard swimming pools, firearms, kerosene heaters, and gang activity), school environment, and developmental factors.

Suicide (Chapter 362) rates have been increasing among 10- to 19-year-olds since 1999, and suicide is now the second leading cause of death among youth 10- to 14-year-olds and 15- to 19-year-olds. In both age groups, Native Americans have the highest rates, followed by White American youth; African American and Asian American youth have substantially lower rates. The rate of attempted suicide is almost five times greater among gay, lesbian, and transgender (sexual minority) students (29%) compared with heterosexual students (6.4%).[3] The estimated ratio of attempted-to-completed suicides among adolescents ranges between 50:1 and 100:1. The most common methods used in suicide attempts are drugs and alcohol, whereas suffocation, hanging, or use of firearms is associated with completed suicides. Suicide death rates caused by firearms are almost seven times higher in 15- to 19-year-old boys than in comparably aged girls.

Homicide is the third leading cause of death among 15- to 19-year-olds and the fourth leading cause among younger adolescents. Among African American males, however, it is the leading cause of death among 15- to 19-year-olds

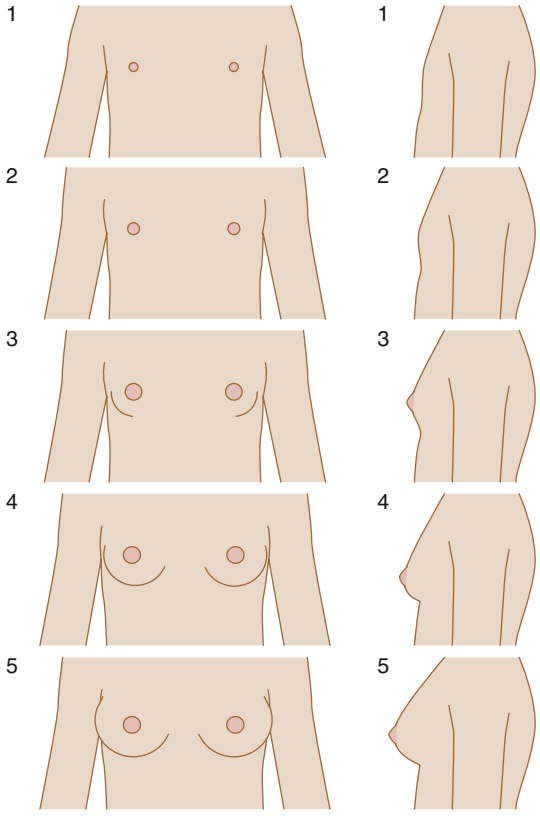
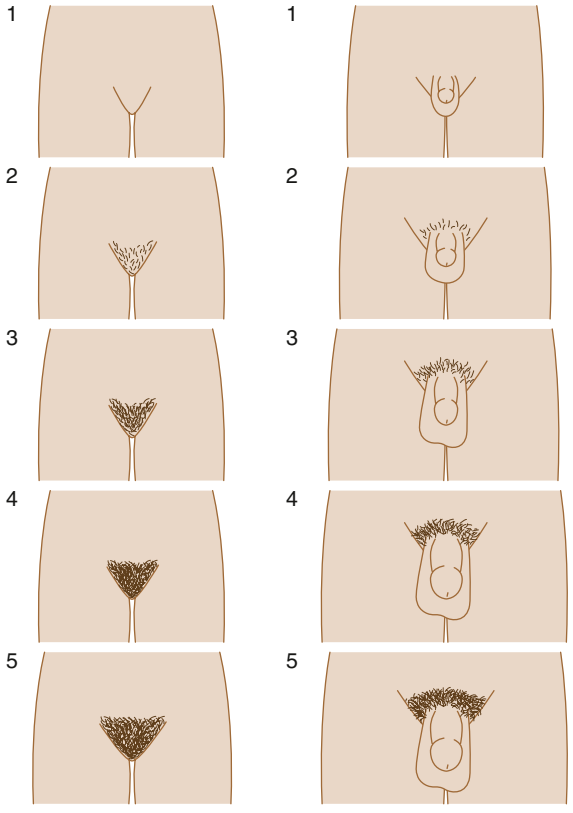
sexual maturity rating



E-FIGURE 21-1. Female breast development. *Sexual maturity rating 1 (SMR 1):* Preadolescent; no glandular tissue. Areola and papilla: Areola conforms to general chest line. *SMR 2:* Breast buds appear; areola is slightly widened and projects as small mound. *SMR 3:* Enlargement of the entire breast with protrusion of the papilla or of the nipple. Breast and areola enlarge with no separation of their contours. *SMR 4:* Enlargement of the breast and projection of areola and papilla as a secondary mound. *SMR 5:* Adult configuration of the breast with protrusion of the nipple; areola no longer projects separately from remainder of breast. (Redrawn from Daniel WA, Paulshock BZ. A physician's guide to sexual maturity rating. *Patient Care*. 1979;30:122. Original illustration by Paul Singh-Roy.)



E-FIGURE 21-2. Female *(left)* and male *(right)* pubic hair development. *Sexual maturity rating 1 (SMR 1):* Prepubertal; no pubic hair. *SMR 2:* Small amount of scanty, long, slightly pigmented, along the base of the scrotum and phallus in the male and the medial border of the labia majora in females. *SMR 3:* Darker, coarser, starts to curl, small amount, extending laterally. *SMR 4:* Coarse, curly; resembles adult type but does not extend to the medial surface of the thighs. *SMR 5:* Abundant, adult-type pattern; hair extends onto the medial aspect of the thighs. *Right*, Male genital development. *SMR 1:* Penis preadolescent. Testicular volume <4 mL. *SMR 2:* Penis slight or no enlargement. Beginning enlargement of testes; testicular volume 4 to 8 mL; scrotal skin reddened, thinner. *SMR 3:* Penis increased in length. Testicular volume 10 to 15 mL. Further enlargement of scrotum. *SMR 4:* Penis larger in breadth, glans penis develops. Testes and scrotum nearly adult; testicular volume 12-20 mL. *SMR 5:* Penis adult size; testicular volume greater than 25 mL. (Redrawn from Daniel WA, Paulshock BZ. A physician's guide to sexual maturity rating. *Patient Care*. 1979;30:122. Original illustration by Paul Singh-Roy.)

(97% involving firearms) and the second leading cause among those 10 to 14 years old (92% firearm-related).

Approximately 1 in 8 9th- to 12th-grade students who dated or "went out with someone" report being the victim of physical or sexual dating violence in the prior 12 months.[4] For both physical and dating violence, the prevalence is higher among females than males (9 versus 7% and 13 versus 4%, respectively). Among 9th- to 12th-grade students, almost 16% report being electronically bullied and 20% report being bullied on school property. Being the victim of bullying is associated with a wide variety of mental health problems. When adolescent bullies become adults, they are more likely than their peers to become violent or abusive towards partners, spouses, and children.

OTHER DISEASES

Excluding intentional and unintentional injuries, cancer is the leading cause of death in adolescents. Cancers of major importance in adolescents include Hodgkin lymphoma (Chapter 172), germ cell tumors (Chapter 185), central nervous system tumors (Chapter 175), non-Hodgkin lymphoma (Chapter 171), thyroid cancer (Chapter 207), malignant melanoma (Chapter 188), and acute lymphoblastic leukemia (Chapter 168).

In adolescents, the course of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection tends to be much milder than in adults, but severe illness, death, and long-term adverse effects can occur.[5] Vaccines against SARS-CoV-2 are at least as effective in adolescents as in young adults.[6]

APPROACH TO THE ADOLESCENT PATIENT

When interviewing adolescent patients, the clinician should consider their physical, cognitive, and psychosocial developmental stage; their growing autonomy and increasing role in taking responsibility for managing their own health and well-being; and their individual progression from childhood to adulthood. Chronologic age is not a guarantee that all adolescents will be at the same stage of development. The clinician should offer adolescent health care in a sensitive, flexible, and developmentally and culturally appropriate manner.

The clinician can meet with the adolescent alone at first to give the message that the adolescent is the patient and the clinician is most eager to hear what the adolescent has to say. This is also an opportunity to assess the adolescent's capacity for autonomous decision making. Conversely, the clinician can meet with the adolescent and their parents or guardians together for the initial part of the interview and then meet with the adolescent alone; this approach permits the clinician to develop an understanding of the reason for the visit from the perspective of the adolescent and the adolescent's parents or guardians and to communicate that input from both the adolescent and the parents or guardians is highly valued. This approach also provides an opportunity for the clinician to observe the interaction between the adolescent and parents or guardians. The final approach to the interview is to greet the adolescent and family and request a meeting with the parents or guardians alone. This approach allows the parents or guardians to discuss concerns about the adolescent that they may not feel comfortable raising in the presence of the adolescent. Having this information may improve the focus of the visit. In this approach, the encounter with the parents or guardians is then followed by the clinician's meeting with the adolescent alone. With this interview structure, it is important that the adolescent be present from the time the adolescent meets with the clinician until the end of the visit, so that the adolescent does not perceive a breach of confidentiality.

CONFIDENTIALITY

Issues of consent and confidentiality are central in the clinician-adolescent interaction. When confidentiality is guaranteed, adolescents are more likely to seek necessary medical care, to disclose sensitive information, and to trust their clinician. Under these circumstances, most adolescents will involve their parents in their care at some point. Parents appreciate education about the concept of confidentiality and recognize the importance of allowing the adolescent the opportunity to speak alone with the clinician. Confidentiality is also important for clinicians to make an accurate diagnosis and to provide treatment.

Confidentiality and defining the limits of confidentiality should be discussed with the adolescent and their parents or guardians at the beginning of the interview. The adolescent and family need to know that the clinician will intervene if the clinician believes that the adolescent's actions may cause the adolescent, or another person, significant harm or that the adolescent is in imminent danger. Examples of situations in which the clinician would not maintain confidentiality when dealing with young people include disclosure of current suicidal or homicidal intent. The legal definition of confidentiality varies, depending on geographic location, and clinicians should be familiar with local laws.

Another goal of the interview is to build rapport with the adolescent and their parents or guardians. Clinicians can establish rapport at the start of the interview by creating an environment that is nonjudgmental, unintimidating, and supportive. It is helpful to encourage the adolescent to talk about themself—friends, hobbies, school. The clinician should listen carefully to the adolescent's statements and feelings. Sensitivity to and understanding of the adolescent's developmental stage, sexual orientation, gender identity, and cultural background are important in interviewing and interpreting answers accurately. The clinician should be respectful of the adolescent's growing need to be independent and desire to be treated as an individual person. Taking the time to build rapport is key to engaging the adolescent in a discussion of their personal health concerns with the clinician.

PREVENTIVE HEALTH CARE

Preventive health care for adolescents (Chapters 12 and 15) should promote physical and mental health and healthy physical, psychological, and social growth and development. Positive behaviors such as exercise (Chapter 14) and nutritious eating (Chapter 13) should be encouraged, and health risk behaviors such as unsafe driving, high-risk sexual behaviors, and use of tobacco (Chapter 363), drugs, and alcohol (Chapter 364) should be discouraged. Because lifelong health habits are established during adolescence, it is an important time to invest in health promotion and preventive services.

The U.S. Preventive Services Task Force recommends screening and counseling of all adolescents about depression[7] and obesity and ensuring that all adolescents are up-to-date on their immunizations for tetanus, diphtheria, pertussis, varicella, measles, mumps, rubella, hepatitis A and B, meningococcus (A, C, Y, W-135), influenza, polio, and human papillomavirus (HPV; Chapter 15). In addition, at-risk adolescents should be counseled about sexually transmitted infections (e.g., human immunodeficiency virus [HIV], chlamydia, gonorrhea, and syphilis) and advised about immunizations for pneumococcus and meningococcal serotype B.

COMPONENTS OF THE ADOLESCENT CARE HEALTH VISIT

History

Open-ended, nonjudgmental, developmentally appropriate, and gender-neutral questions help put the adolescent at ease and produce informative answers (Chapter 12). In addition to a standard medical history, the assessment should include a psychosocial history from the adolescent, either through a screening questionnaire or during the interview with the adolescent alone. The HEEADSSS assessment, a valuable screening tool for obtaining a comprehensive psychosocial history, covers the following topics:

- **H**ome: family members, living arrangements, and relationships
- **E**ducation/**E**mployment: academic or vocational success and future plans
- **E**ating: concerns about weight or body image or disordered eating attitudes and behaviors; dietary intake
- **A**ctivities: recreational activities, dating, and relationships
- **D**rugs: use of tobacco or e-cigarettes, alcohol, illicit drugs, anabolic steroids, nonmedical use of prescription medications, and driving while intoxicated or after using drugs
- **S**exuality: sexual orientation, sexual behaviors (including abstinence), and sexual abuse
- **S**uicide (mental health): feelings of sadness, loneliness, depression; or suicidal ideation, attempts, and nonsuicidal self-injury
- **S**afety: risk of unintentional injury or violence, fighting; or weapon carrying; seat belts when driving motor vehicles; bicycle helmets, and sports-related protective gear.

Physical Examination

In general, the adolescent physical examination should occur without a parent or guardian present. In some situations, the adolescent is asked whether they would prefer to have a chaperone in the room during the physical examination. A male clinician should request that a female chaperone be present during the physical examination of a female patient, especially during the breast and genital examination. In theory, a female clinician should request a male chaperone be present during the genital examination of a male patient.

Care should be taken to ensure the adolescent's privacy. Providing an examination gown that covers the trunk and genital area is important. Talking with the adolescent during the examination also tends to increase comfort; explaining the procedures and commenting on the results are helpful. A comprehensive physical examination (Chapter 12) should include measuring the adolescent's weight and height, calculating their body mass index, plotting these measurements on standardized growth charts, and determining the adolescent's SMR.

Adolescent cardiovascular risk factors are associated with adult cardiovascular events.[8] However, the U.S. Preventive Services Task Force currently states that it cannot make recommendations for or against screening adolescents for high blood pressure.[9]

A thorough sexual history must be obtained to determine which anatomic sites (oral, anal, vaginal, urethral) should be screened for sexually transmitted infections. Annual screening for *Chlamydia trachomatis* and *Neisseria gonorrhoeae* is recommended for sexually active adolescents. A self-collected vaginal swab is the preferred specimen for testing women, whereas a first-catch urine specimen is preferred for men to screen for urethral infection (and is acceptable for women as well). Adolescents 13 years and older should be screened at least once for HIV infection. Screening intervals for all sexually transmitted infections should be based on the patient's sexual behaviors.

Routine cervical cancer screening is not recommended in adolescents.[10] However, screening is appropriate in young women with HIV infection, human papillomavirus infection, immune deficiency, or a prior abnormal cervical screening result. Indications for a pelvic examination in an adolescent include symptoms of vaginal or uterine infection, menstrual irregularities (e.g., amenorrhea, dysfunctional uterine bleeding, menorrhagia, and severe dysmenorrhea), undiagnosed abdominal or pelvic pain, tenderness, mass, trauma, sexual abuse, or assault.

Conclusion of the Health Visit

At the conclusion of the adolescent health visit, the clinician should review the findings with the adolescent and talk about what happens next. The adolescent should have the opportunity to ask questions, get clarification, make comments, and respond to suggestions. The clinician should discuss with the adolescent what information will remain confidential. The clinician should then meet with the adolescent and the parents or guardians (if they have accompanied the adolescent to the health visit) to review the outcomes and to discuss the nonconfidential issues.

SEXUAL AND REPRODUCTIVE HEALTH

Care related to sexual and reproductive health includes issues of adolescent sexual development, sexual orientation, sexual behaviors, gender identity (Chapter 214), pregnancy, and, if indicated, contraception. When obtaining a sexual history, it is important that clinicians avoid assumptions about a teen's gender identity, gender expression, or sexual attraction; doing so will likely preclude receiving correct information.

In the United States, the percentage of teens having sex before the age of 13 is 3.4%: 2.0% of girls and 4.8% of boys.[11] The proportion of young people who have had sexual intercourse increases as they age through adolescence: one in five 15-year-olds and two-thirds of 18-year-olds report having had sex.[12] About 40% of adolescents aged 15 to 19 years reported ever having had penile-vaginal intercourse, 45% ever having had oral sex with a different-sex partner, and 9% ever having had anal sex with a different-sex partner. Among adolescents aged 15 to 19 years who had had penile-vaginal sex, 75% of females and 48% of males reported that their first intercourse was with a steady partner.[13] About 10% of adolescents have had four or more sex partners during their lives, and over 50% of sexually active high-school students report condom use during their last sexual encounter. Nearly 12% of adolescent females between 9th and 12th grade report having been forced to have intercourse. Adolescents are more likely to report engaging in oral than in vaginal sex because they perceive oral sex as significantly less risky (fewer health, social, and emotional consequences) than vaginal sex, but adolescents who engage in oral sex also are more likely to engage in vaginal sex.

In 2019, about 170,000 babies were born to women aged 15 to 19 years in the United States. This birth rate of 16.7/1,000 women in this age group represented an historic low for the United States.[14] Even so, the United States has the highest adolescent birth rate of any developed country. Adolescent pregnancy is more common among American Indian/Alaska Native, Black, and Hispanic girls, as well as among girls from low-income families. Abortion rates in this age group have decreased by almost 50% since 1990, mostly attributable to decreased sexual activity and increased use of effective contraception.

CONTRACEPTION

The use of effective contraceptive methods is a cornerstone of preventing adolescent pregnancy. Sexually active teens require ready access to confidential care that offers effective, safe, and affordable types of birth control. The most commonly used contraceptive method in adolescents is the condom, followed by withdrawal and oral contraceptive pills.[15] Hormonal delivery systems, such as transdermal patches, vaginal rings, and long-acting reversible contraceptives, are convenient and effective (Chapter 220). Long-acting reversible contraceptive methods (intrauterine devices and contraceptive implants) are now recommended as the contraceptive method of choice for young women because of their high effectiveness. In choosing a method of contraception, dual protection against HIV and other sexually transmitted infections should be recommended. Routine counseling about and advance provision of emergency contraception is an important part of the public health strategy to reduce teen pregnancy rates (Chapter 220).

SEXUALLY TRANSMITTED INFECTIONS

Young people ages 15 to 24 account for over half (55%) of all new sexually transmitted infections in the United States (Chapter 264). In 2019, adolescents 15 to 19 years of age accounted for 25% of the reported cases of chlamydia (Chapter 294) and 15% of the cases of gonorrhea (Chapter 275) in the United States. The overall prevalence of *Chlamydia trachomatis* infections among 14- to 19-year-olds is approximately 2%, but the prevalence varies and is higher among young women than men. In adolescents, HIV infection (Chapter 353) is contracted primarily as a sexually transmitted infection, and youth 13 to 24 years of age represent over 20% of all new diagnoses of HIV infection in the United States. HPV (Chapter 344), which is the most prevalent of all sexually transmitted infections in 15- to 24-year-olds, has a prevalence of about 20% in adolescent girls 14 to 17 years of age. HIV and syphilis are of particular concern among African American and Hispanic male adolescents with same-sex partners.

Adolescents are at increased risk for acquiring sexually transmitted infections for several reasons, including elevated rates among sex partners and inconsistent or incorrect condom use. Sexual minority youth may have particular difficulty accessing appropriate sexual health services. Adolescent girls may have persistent cervical columnar epithelium that is more susceptible than squamous epithelium to infection with *Neisseria gonorrhoeae, Chlamydia trachomatis*, and HPV as well as lower levels of immunoglobulin A in their cervical mucus. For many adolescents, treatment may be delayed owing to an inability to access confidential health care services, lack of health insurance, stigma, shame, poverty, and drug use.

Chlamydial infections (Chapter 294) are overwhelmingly asymptomatic. When symptoms are present, they may be so mild or short-lived that they are easily ignored. Otherwise, clinical presentations and treatments of sexually transmitted infections (Chapter 264) in adolescents are similar to those in adults.

To maximize the likelihood of successful treatment of these infections, an observed single-dose therapy is preferred, when available. In addition, whenever possible, expedited partner therapy, which is the treatment of sexual partners without requiring a prior clinical evaluation or prevention counseling, reduces the risk of recurrent sexually transmitted infections better than standard management and should be used within 60 days wherever state law permits. Clinicians should consider the use of expedited partner therapy for partners exposed to heterosexual males and females with chlamydia or gonorrhea infections, especially when in-person evaluation and treatment are unlikely (Chapter 264).[16] For prevention, the U.S. Preventive Services Task Force recommends behavioral counseling for sexually active adolescents.[17]

OBESITY

The prevalence of obesity among adolescents between ages 16 and 19 years is 20%.[18] Obese adolescents are significantly more likely to become severely obese in adulthood. The health consequences of adolescent obesity include sleep apnea, diabetes and its complications,[19] and cardiovascular diseases. Interventions should focus on changing behavior, modifying diet,[A1] increasing physical activity, reducing screen time, assessing for obesity-related physical and mental health issues, and improving sleep patterns. Pharmacotherapy can be considered after a formal program of intensive lifestyle modifications has failed to limit weight gain or to ameliorate comorbidities.[A2] Bariatric surgery may be considered as an option for adolescents with severe obesity (Chapter 201).

MENTAL HEALTH

About 25% of female adolescents and about 10% of male adolescents in the United States have depression.[20] Approximately 75% of lifetime cases of depression[21] and anxiety (Chapter 362) start by age 24 years. The most common mental disorders in adolescents (age 13 to 18 years) in the United States by lifetime prevalence are anxiety (32%), behavior (19%), and mood disorders (14%). About 10% of adolescents have attention-deficit/hyperactivity disorder,[22] about half of whom are on medications.[23] Adolescents diagnosed with one of these mental health problems often have other comorbid disorders.

Screening for anxiety[24] and depression[25] is recommended in adolescents. Left undiagnosed or untreated, these disorders can influence development, education, social relationships, and participation in the workforce.

EATING DISORDERS

Eating disorders (Chapter 200) commonly begin during adolescence. For adolescent-onset eating disorders, early recognition and aggressive treatment are critical to a successful outcome. The medical complications of eating disorders in adolescents include faltering growth, pubertal delay, low bone mineral density, and changes in brain structure and cognitive function. These complications, which occur early in the disease process, may not be completely reversible.

The goals of treatment are to restore physical health, normal eating behavior patterns, and mental health and to reduce the impact of the eating disorder on the quality of life. Adolescents should be treated at a facility where the health professionals understand eating disorders and have experience in treating adolescents. Successful management strategies for adolescents with eating disorders include early restoration of a normal nutritional and physiologic state, involvement of the family in the treatment, and incorporation of an interdisciplinary team in the treatment. Family-based therapy is an effective first-line, outpatient treatment for adolescents with eating disorders and helps protect against relapse.

SUBSTANCE USE AND SUBSTANCE USE DISORDERS

Nearly half of adolescents try an illicit drug (Chapter 365) by the time they finish high school. Just over 60% of adolescents consume alcohol (Chapter 364) by the end of high school, and about 40% report having been drunk at least once in their life. Adolescents who begin using alcohol or drugs before 15 years of age are more than five times more likely to develop an addiction later in life compared with those who first use alcohol at 21 years of age.

Nearly 30% of 12th-grade students report vaping in the last 30 days, with 25% vaping nicotine and 12% vaping marijuana. About 25% of U.S. adolescents have used marijuana in the past year, a percentage that has remained relatively stable over the last decade with an increasing proportion using e-cigarettes or vaping systems as the delivery device. Similarly, adolescents are now more likely to use e-cigarettes than to smoke conventional cigarettes (Chapter 363); however, those who use e-cigarettes are more likely than nonusers to initiate conventional cigarette use as well.[26] In 2004, almost 10% of 12th-graders reported nonmedical use of prescription opioids (Chapter 365), but that number dropped to 2% in 2020.[27]

Adolescent drug use is the result of a complex interaction among genetic, social, environmental, and personal risk factors. Boys tend to initiate drug and alcohol use at younger ages than girls do, but once girls begin to experiment, they are just as likely as boys to use drugs. Boys are more likely to consume marijuana, steroids, and smokeless tobacco, whereas girls are more likely to use amphetamines and methamphetamine.

Adolescents with poor self-esteem and low motivation, as well as those without an attachment to school and/or with poor academic achievement, have a greater propensity for alcohol and drug use compared with those without these characteristics. Adolescents with a family history of alcohol or other drug use are also at greater risk. Adolescents are less likely to succumb to external pressures toward drug use if they have a strong sense of attachment to parents who clearly communicate their disapproval of drug use.

Signs and symptoms suggestive of substance use or substance use disorders include changes in physical appearance, poor hygiene or dress, wearing long-sleeved shirts to hide scarring at injection sites, persistent cough or bronchitis, difficulty sleeping, sudden weight loss or weight gain, sudden changes in personality, aggressive behavior, irritability, nervousness, giddiness, changes in peer group, increased isolation from peers or family, depression, loss of interest in once-favorite activities, decline in performance or attendance at school or work, forgetfulness, increased secretiveness, money or objects disappearing from the household, and prescription drugs that seem to be used up too quickly.

A validated screening tool for alcohol and substance use (Table 21-2) should be used in adolescents.[28] Those answering yes to one question should receive feedback regarding the adverse effects of substance use. Those who answer yes to two or more questions are at high risk for substance use problems and require further assessment or referral (Chapters 364 and 365).[A3] Urine drug testing has low sensitivity for detection of drug use, and there is no consensus about its role for screening of adolescents.

Alcohol and drug use contributes to more than 40% of adolescent deaths from motor vehicle crashes, to suicide attempts, and to an increased risk for subsequent use and dependence and related problems in adulthood. Historically, treatment for substance use disorders in adolescents and young adults has been based on abstinence. More recently, however, a harm-reduction approach has gained acceptance. Adolescents discontinue drug and alcohol use mainly because of concern about their negative effects, and community-based interventions can be effective. Individual interventions appear to have a larger effect size than family-based interventions[A4] in reducing alcohol abuse, with the effect size decreasing over time.

TABLE 21-2 CRAFFT SCREENING TOOL FOR DRUG AND ALCOHOL USE IN ADOLESCENTS

The adolescent is instructed, "Please answer these next questions honestly. Your answers will be kept confidential. During the past 12 months, did you …"
- Drink any alcohol (more than a few sips)?
- Smoke any marijuana or hashish?
- Use anything else to get high?

If the adolescent answers no to the three opening questions, the provider only needs to ask the adolescent the first question—the CAR question. If the adolescent answers yes to any one or more of the three opening questions, the provider asks all six CRAFFT questions.
- **C**—Have you ever ridden in a CAR driven by someone (including yourself) who was "high" or had been using alcohol or drugs?
- **R**—Do you ever use alcohol or drugs to RELAX, feel better about yourself, or fit in?
- **A**—Do you ever use alcohol/drugs while you are by yourself, ALONE?
- **F**—Do you ever FORGET things you did while using alcohol or drugs?
- **F**—Do your family or FRIENDS ever tell you that you should cut down on your drinking or drug use?
- **T**—Have you gotten into TROUBLE while you were using alcohol or drugs?

CRAFFT is a mnemonic acronym of the first letters of key words in the six screening questions. The questions should be asked exactly as written.

CHRONIC ILLNESS AND TRANSITION

The prevalence of chronic diseases in adolescents has increased significantly because advances in medical technology and treatments have increased the survival of young people with childhood diseases formerly considered lethal. About 18% of adolescents in the United States live with a chronic illness. Chronic illness may affect the adolescent's development, or the adolescent's development may affect the illness. For example, cystic fibrosis (Chapter 77) may delay puberty and hinder normal peer development. Puberty can exacerbate diabetes mellitus (Chapter 210). Increased risk-taking by adolescents with diabetes, asthma, or chronic renal failure can hinder their compliance with their medication regimen.

Adolescents in general, and those with special health care needs in particular, require a smooth, seamless, coordinated, and developmentally appropriate transition to support their engagement in the adult health care system.[29] The patient, family, and pediatric and adult health care systems should view the transition as a natural part of the developmental process of care for all adolescents. The recommended elements of a transition plan include early individualized planning and preparation of patient, family, and health care teams; tailored written transition plans; coordination by both the transferring and receiving physicians; introductory meetings for young adults with their new providers before transfer; transfer at a time of disease stability rather than during a period of instability; and the introduction of transition coordinators who act as liaisons between the pediatric and adult health care system.

22 EPIDEMIOLOGY OF AGING

LOUISE ARONSON

DEMOGRAPHY

For decades, the world's population has aged at an unprecedented rate. Both proportions and absolute numbers of people living into old age have increased. As of 2020, 1 billion people were age 60 years or older, and by 2050 people over age 65 years are projected to account for 1 in 6 people worldwide. Between 1990 and 2019, people over age 80 nearly tripled, a number expected to triple again by 2050, thereby reaching 426 million. As a result of these marked shifts, the World Health Organization declared 2020 to 2030 the Decade of Healthy Ageing, and the United Nations has recognized aging as one of four global population "mega-trends."[1]

In 2021 in the United States, people ages 65 years and older accounted for 16% of the population, and people over age 80 years comprised 4% of the population, with those numbers expected to double and triple, respectively, by 2050.[2] So-called baby boomers (i.e., people born between 1946 and 1964 and one of the largest generations in American history) play a key role in shaping national demographic trends. By the 2030s, when all baby boomers are over age 65 years, older Americans will constitute 21% of the population, and the country will have more elderly people than children. Since millennials (people born between 1981 and 1995) outnumber baby boomers, these trends are projected to continue for generations.

Three demographic factors within this larger transformation have important implications for health. First, marked inequalities in life expectancies persist across ethnic and racial groups (Chapter 4), among sexual minorities, and in geographic location within the United States.[3] Second, a somewhat smaller but still significant gender gap exists in longevity. In 2019, for example, average life expectancy at age 65 years was 18.2 years for males and 20.8 years for females. Third, the longevity curve has flattened since 2010 as a result of a leveling of the decline in mortality from cardiovascular disease (Chapter 40) despite increases in deaths from drug overdose (Chapter 365), suicide (Chapter 362), obesity (Chapter 201), and Alzheimer disease (Chapter 371), as well as the emergence of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2; Chapter 336).[4] Improvements in life expectancy will therefore require attention to social determinants of health across the life span.

DISEASE AND DISABILITY IN OLDER ADULTS

MORBIDITY AND MULTIMORBIDITY

Over 85% of older adults have one or more chronic health conditions (Table 22-1), the most common of which are hypertension (Chapter 64), hyperlipidemia (Chapter 190), arthritis (Chapter 236), heart disease (Chapter 40), and diabetes (Chapter 210). The prevalence of individual diseases varies by sex, race, and ethnicity. For example, more older Black adults than White adults report hypertension (about 70% vs. about 55%), and more women have arthritis than men (about 60% vs. about 45%). Nevertheless, over 82% of adults ages 65 to 74 years and 73% of adults ages 75 years and older describe their overall health as good to excellent. Self-reported health worsens not only with advanced age but also by race; 12 to 14% of Native, Black, and Latino Americans report fair to poor health compared with just over 8% of White or Asian Americans. Over age 70 years, nearly 14% of Americans have dementia (Chapter 371) and a majority have sensory impairments, including problems with balance (75%), hearing (26%), and vision (15%). The lifetime risk of dementia increases with age, is higher in women than in men (for reasons that include greater longevity as well as hormonal and environmental factors), and is nearly two times higher in Black adults than White adults.

Multimorbidity, which is the state of having multiple comorbid conditions, is the norm with advancing age. About 65% of adults over age 65 years have two or more chronic health conditions, nearly a quarter have four or more such conditions, and the prevalence of multiple chronic conditions is increasing. After adjustment for other factors, Black adults have earliest onset and highest prevalence of multimorbidity, whereas Latino adults develop multimorbidity most rapidly with aging. Quality care of older adults requires consideration of sociodemographic risk, the impact of the treatment of one condition on others, the masking of diseases by symptoms of other diseases, and burden of the treatment.

The degree of multimorbidity predicts future disability. The proportion of older adults with self-reported difficulty in activities of daily living increases stepwise as their number of medical conditions increases. Multimorbidity is also associated with poorer lower extremity strength and balance, which are predictors of disability, and slower gait speed, which is a powerful predictor of mortality in old age. Multiple chronic diseases have more than an additive effect on physical functioning and hence disability.

GERIATRIC SYNDROMES

Geriatric syndromes (Chapter 24), which are common and highly morbid conditions in older adults, are not linked to a single disease or pathologic process but rather occur when accumulated impairments across multiple domains result in a single, recognizable phenomenon. For example, falls (Chapter 24) occur in people with a wide range of risk factors: poor vision, foot problems, cognitive impairment, disorders of gait and balance, fear of falling, sarcopenia, neurologic diseases, polypharmacy, and medications that can cause orthostatic hypotension. Other geriatric syndromes include urinary incontinence (Chapter 115), frailty (Chapter 24), impaired sleep (Chapter 374), delirium (Chapter 361), pressure ulcers (Chapter 24), cognitive impairment (Chapter 371), and malnutrition (Chapter 197). Geriatric syndromes adversely affect health outcomes and may be caused or exacerbated by medical treatments.

SUBCLINICAL DISEASE

The risks of disability and mortality among older adults are elevated by asymptomatic or unrecognized disease. Nonspecific symptoms may be inaccurately attributed to aging or a comorbid condition. For example, magnetic resonance imaging reveals subclinical vascular changes consistent with a prior stroke in about one third of older adults without a history of stroke. Although subclinical cardiovascular disease doubles the risk of falls, frailty, dementia, and death, when and how to intervene to prevent these outcomes remains unclear. Noninvasive testing also yields higher rates of conditions such as hypothyroidism (Chapter 207), peripheral arterial disease (Chapter 65), chronic obstructive pulmonary disease (Chapter 76), and osteoarthritis (Chapter 241) than are documented clinically, perhaps in part because other limitations mask their subclinical impact.

OBESITY

Obesity (Chapter 201) is a major cause of preventable life-years lost, and its impact on morbidity (e.g., physical limitations, diabetes) and mortality (e.g., cardiovascular disease, cancer) increases with age. Over age 60 years, about one third of White adults, 40% of Latino adults, and 50% of Black adults are obese. Obesity disproportionately affects older women, especially Black women and low-income women, in whom it increases the risk of disability, low quality of life, nursing home placement, and death. However, the prevalence of obesity declines after age 75 years, in part because of selective survivorship and in part because of the increasing prevalence of serious comorbid diseases that result from the pro-inflammatory state of obesity.

TABLE 22-1 U.S. ADULTS WITH CHRONIC CONDITIONS, MULTIMORBIDITY, 2018

	NO CHRONIC CONDITIONS		*1 CHRONIC CONDITION*		*≥2 CHRONIC CONDITIONS*	
AGE	**% POPULATION**	**N**	**% POPULATION**	**N**	**% POPULATION**	**N**
18 to 44 years	73%	83,444	21%	23,841	7%	7,723
45 to 64 years	37%	30,404	30%	25,250	33%	27,383

DISABILITY

Disability in older adults can be slowly progressive and chronic (e.g., arthritis), subacute and potentially reversible (e.g., post-hospitalization), or sudden and catastrophic (e.g., after a stroke). Levels of disability range from challenges in work, social, or recreational activities, thereby requiring adaptation or substitution, to an inability to be independent in household tasks, to the loss of basic self-care capabilities and the need for long-term personal care (see Chapter 23).

Fortunately, most older adults are not disabled. Although some degree of loss in physical function with advancing age is inevitable, the effects of age are highly variable, both between and within individuals. For example, self-reported physical limitations are about 6.5% through age 45 years, but they increase to 17% between ages 46 to 64 years, to 27% at age 65 years, and to 45% at age 75 years and beyond. After age 65 years, the prevalence of physical disability is higher among women in each age subgroup, as well as in American Indians, Alaska Natives, Latinos, people below the federal poverty level, and people living in the South U.S. Census region. Between the ages of 65 to 74 years, just 4% of Americans need personal care, but that number rises to 21% in Americans over age 85 years.

Noncatastrophic disability has a preclinical phase, during which people limit or modify their function but are not yet disabled. The onset of disability occurs with frequent transitions between independent and dependent states, thereby often offering multiple opportunities for intervention.[5] Major disabling conditions include arthritis, cardiovascular disease, chronic back pain, and dementia. However, joint and cardiac disease do not always cause limitations in the elderly, whereas sensory impairment and falls have substantial impact on disability.

FRAILTY

Frailty (Chapter 24) is defined as an age-related syndrome of decreased physiologic reserve, increased vulnerability to stress, and adverse health outcomes. Its phenotype has been described as including at least three of the following: weakness, fatigue, low activity, slow movement, and weight loss.[6] Frailty is also characterized by poor physical function, accumulation of physical deficits, and the cumulative burden of disease. Loss of muscle mass, which is termed sarcopenia, is also a key component of frailty.[7] Experimental data suggest that sestrins, which are stress-induced regulators that affect cell metabolism, may be critical for maintaining muscle mass and strength.

The prevalence of frailty, which increases with age, is under 5% below age 70 years but rises steeply thereafter to over 30% above age 80 years. In all older age groups, frailty is more common in women than men, and it is more prevalent in populations with high rates of chronic disease and socio-demographic disadvantage.[8] Importantly, frailty is not a steady state; both progression and reversion are common, although it eventually usually becomes a pre-death condition.

In clinical settings, frailty can be assessed using a validated instrument (see Table 24-1). Weakness can be assessed in an office setting by measuring grip strength (<30 kg in men and <20 kg in women). Although frailty itself is a risk factor for poorer outcomes and high health care costs, it also is associated with falls, fractures, cognitive decline, depression, low quality of life, loneliness, disability, nursing home admission, and hospitalization.

MORTALITY

Mortality rises with age. U.S. death rates are 1.7% per year between the ages of 65 to 74 years, increasing to 4.3% per year between the ages of 75 to 84 years, and to 13.2% per year in Americans age 85 years and older.[9] Before the coronavirus-2019 (COVID-19) pandemic, the top five causes of death for Americans ages 65 and older were cardiovascular disease (37%), cancer (about 27%), chronic lower respiratory disease (about 8%), cerebrovascular disease (about 8%), and Alzheimer disease (about 8%). Since 1980, cardiovascular disease and cancer have remained the top causes of death, whereas death rates for Alzheimer disease, diabetes, and unintentional injuries have increased (Table 22-1). Cancer was the leading cause of death and diabetes the fifth most common among the young-old ages 65 to 74 years, whereas Alzheimer disease and stroke are more common in the old-old ages 85 years and older. In 2020, however, COVID-19 became the third leading cause of death among all older age subgroups (Fig. 22-1),[10] and especially in frail elderly.[11]

HEALTHY AGING

LONGEVITY AND HEALTHY AGING

About 15 to 25% of longevity is estimated to be heritable. Other key determinants include a mother's health during pregnancy, lifetime exposures to infectious diseases and environmental hazards, psychosocial stress, nutrition (Chapter 13), physical activity (Chapter 14), and avoidance of smoking

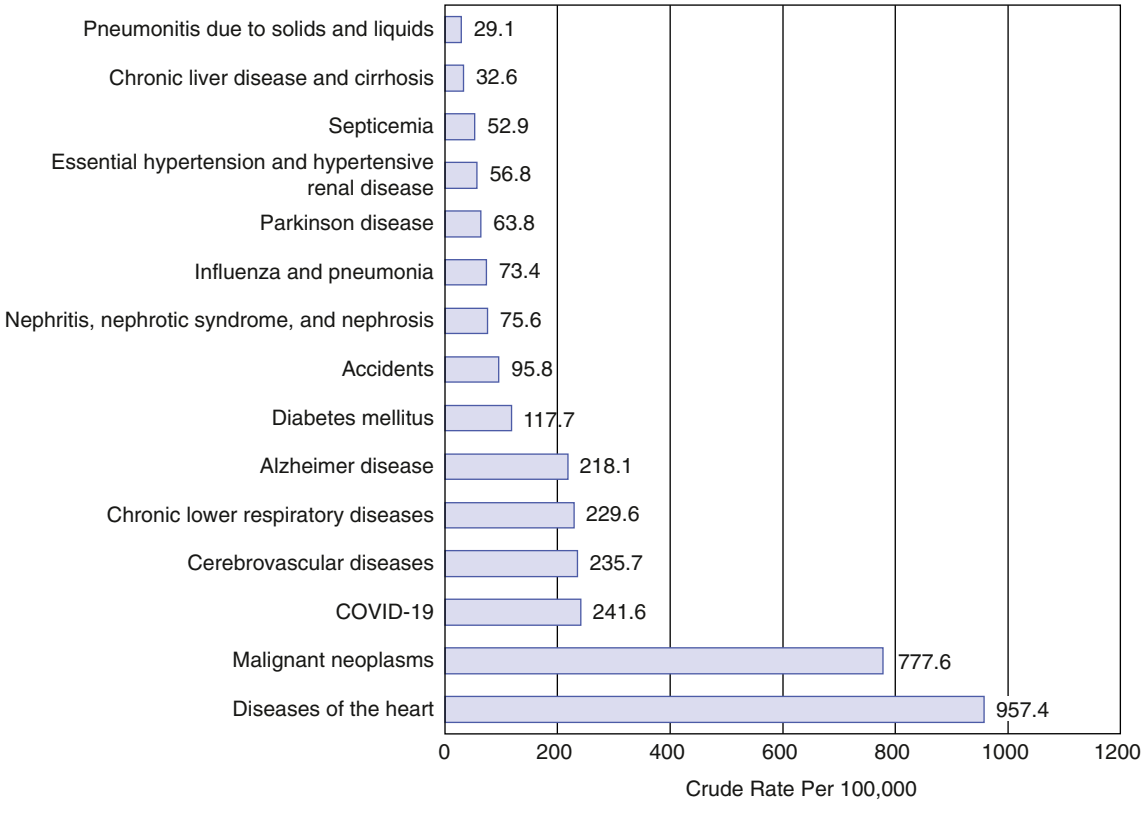

FIGURE 22-1. Underlying causes of death in Americans over age 65 years. (Centers for Disease Control and Prevention, National Center for Health Statistics. (Chapter 363) and drugs of abuse (Chapter 365). Primary molecular pathways involved in aging include insulin and insulin growth factor-1, sirtuins, mechanistic target of rapamycin (mTOR), and AMP-activating protein kinase (AMPK). Each of these mechanisms affects autophagy, the catabolic process that enables cells to recycle dysfunctional material and maintain energy homeostasis. Metabolism, proteostasis, inflammation, epigenetics, macromolecular damage, and stem cells are among the critical, interrelated factors affecting healthy aging.

Emerging geroscience suggests the possibility that biological rate of aging may be slowed by nutritional, behavioral, genetic, and pharmacological interventions. Senolytics are compounds, such as flavonoids, that are being evaluated as potential supplements to slow the progression of aging.[12] Although many hormone levels decline with aging, hormone replacement with estrogen (Chapter 222), growth hormone (Chapter 205), testosterone (Chapter 216), and adrenal androgens (Chapter 208) have not been proven beneficial for longevity and have known harms.

Critical to consideration of longevity is the concept of "health span," defined by the World Health Organization as the average number of years lived in full health. Worldwide, life expectancy at age 60 years is 18.3 years in men and 21 years in women, but health life expectancy is only about 14 years in men and 16 years in women (Table 22-2).

Between 1991 and 2018, the health span of older Americans increased, with fewer elderly individuals reporting fair or poor health. Despite these overall gains, however, considerable disparities persist based on economic status, with fair or poor health reported by 21% of Americans age 65 years and older below the poverty level compared with just 4% of Americans in that age range with incomes at 400% of the poverty level or higher.

PREVENTION

Intensive blood pressure control to systolic blood pressure to less than 130 mm Hg lowers cardiovascular events in adults ages 60 to 80 years.[A1] Statins effectively reduce cardiovascular and all-cause mortality when used for primary prevention, even in individuals up to at least age 75 years.[A2] In healthy elderly, low-dose aspirin not only does not improve disability-free survival but also actually increases all-cause mortality.[A3] Antiresorptive and anabolic agents can slow the progression of osteoporosis and reduce the risk of fractures in women.[A4] Multifactorial interventions to prevent falls, fractures, and serious fall injuries do not appear to be helpful as currently designed.[A5,A6] Exercise reduces functional decline in community-dwelling elderly persons.[A7] Tai Chi continues to be the most effective exercise for preventing falls in community-dwelling older adults, whereas resistance training is useful to reduce the risk of disability.[A8] Biobehavioral approaches can decrease disability in low-income elders.[A9] Hearing aids significantly improve hearing-related function, but their long-term benefit to prevent disability or dementia is not yet known.[A10]

23 GERIATRIC ASSESSMENT

C. SETH LANDEFELD

The goal of geriatric assessment is to improve quality of life, independence, and longevity by identifying conditions that may be ameliorated and by informing patients' decisions. Geriatric assessment evaluates specific domains that are often impaired in older people and that reduce quality of life, ability to live independently, and life expectancy; and the personal and social context of the older person.

RATIONALE

The premise of geriatric assessment is that older individuals desire "life, liberty, and the pursuit of happiness." Fulfillment of these desires depends on the older person's abilities, their environment, and the person-environment fit, all of which should be assessed and managed to achieve the older person's goals.

Geriatric assessment and management by a clinician or multidisciplinary team identifies conditions that are often undetected but can be ameliorated; they also provide information about prognosis, patients' values, and preferences.[1] Geriatric assessment improves outcomes in hospitalized older adults and in older adults with advanced cancer, and possibly in others.[A1–A5]

FUNCTION

Decline in the function of every organ system occurs at a rate of about 1% per year after age 30 years. Geriatric assessment evaluates functions that directly affect how older people live in the world each day. These functions generally depend on the central or peripheral nervous system, although they can be affected by dysfunction in other organ systems.

23 GERIATRIC ASSESSMENT

C. SETH LANDEFELD

The goal of geriatric assessment is to improve quality of life, independence, and longevity by identifying conditions that may be ameliorated and by informing patients' decisions. Geriatric assessment evaluates specific domains that are often impaired in older people and that reduce quality of life, ability to live independently, and life expectancy; and the personal and social context of the older person.

RATIONALE

The premise of geriatric assessment is that older individuals desire "life, liberty, and the pursuit of happiness." Fulfillment of these desires depends on the older person's abilities, their environment, and the person-environment fit, all of which should be assessed and managed to achieve the older person's goals.

Geriatric assessment and management by a clinician or multidisciplinary team identifies conditions that are often undetected but can be ameliorated; they also provide information about prognosis, patients' values, and preferences.[1] Geriatric assessment improves outcomes in hospitalized older adults and in older adults with advanced cancer, and possibly in others.[A1–A5]

FUNCTION

Decline in the function of every organ system occurs at a rate of about 1% per year after age 30 years. Geriatric assessment evaluates functions that directly affect how older people live in the world each day. These functions generally depend on the central or peripheral nervous system, although they can be affected by dysfunction in other organ systems.

ABSTRACT

Geriatric assessment aims to improve quality of life, independence, and longevity of older people by identifying conditions that may be ameliorated, informing a management plan, and guiding patients' decisions. Geriatric assessment broadens conventional management of chronic diseases and focuses on geriatric syndromes that worsen quality of life and shorten it. Geriatric assessment has four components. First, it assesses functions that are often impaired in older people. These functions include the ability to perform activities needed to live independently (functional status), continence, cognition, competency, mood, hearing, vision, mobility, risk of fall, nutrition, and sexual function. Medications are assessed, and evidence of self-neglect or abuse is sought. Second, the person's built and social environments are evaluated. Third, prognosis is determined. Fourth, the person's values, goals, and preferences are determined. Recommendations that can improve quality of life and lengthen survival are based on the assessment, as well as the person's prognosis and preferences. Recommendations incorporate preventive services for which evidence confirms that the benefits exceed the harms. Geriatric assessment and management can increase survival, independent living, and quality of life, especially in older people with serious diseases.

KEYWORDS

geriatric assessment
functional status
prognosis
medication review
patient goals and preferences
preventive services for older people

INITIAL OBSERVATION

Geriatric assessment begins with observation of the patient and companions, looking for signs of geriatric syndromes such as dementia (Chapter 371), depression (Chapter 362), impaired mobility (Chapter 24), or elder abuse. Is the patient alone or accompanied? Bright or dulled? Well groomed? Conversant? At ease with a companion? Does the patient stand briskly and without assistance? Is the gait normal?

FUNCTIONAL STATUS

Functional status refers to the ability of an individual to perform activities that are needed to fulfill social and community roles. These activities, which are acquired during childhood, are often lost in reverse order with progressive failure of the brain or another organ. For example, children learn first to feed themselves, later to dress, and later to work, whereas a person with dementia may first lose the ability to work, later to dress, and later to feed.

Activities of daily living (ADLs) are performed daily: feeding, maintaining continence, toileting, transferring, bathing, grooming, and dressing. People with an impairment, such as difficulty standing, may maintain independence in ADLs by using an appliance, such as a raised toilet seat and support stand. ADL dependency—needing the help of another person to perform an activity—can be caused by an acute illness but often results from a neurologic condition such as neurodegenerative disease or stroke.

Instrumental ADLs are performed to live at home: preparing meals, housework, laundry, shopping, driving or using public transportation, using the telephone, and handling medications and finances. Dependency in instrumental ADLs can be caused by physical limitations from chronic disease or by dementia (Chapter 371), and it is often an early sign of undiagnosed dementia. Dependency in instrumental ADLs often can be ameliorated by a variety of public and private services (e.g., taxis or rideshare, laundry and cleaning services, and Meals on Wheels).

Dependency in ADLs and instrumental ADLs are present in about 10% and 20%, respectively, of people ages 75 years or older living in the community and are very frequent in hospitalized elders. These dependencies are strong predictors of long-term institutionalization and death.

Advanced ADLs are the ability to fulfill societal, community, and family roles. They can be assessed by asking the person whether they perform an activity, such as playing a musical instrument, or performed it previously. Loss of advanced ADLs may indicate mild cognitive impairment, dementia, or physical limitations.

COGNITION AND COMPETENCY

Mild cognitive impairment does not interfere with independent ADLs. By comparison, dementia (Chapter 371), which is cognitive decline in one or more domains not explained by delirium (Chapter 361) or another mental disorder (Chapter 362, interferes with independence in instrumental ADLs.

The incidence of dementia increases from less than 1% per year at age 65 years to 5% per year at age 85 years. Treating hypertension with a target of 120 mm Hg systolic (Chapter 64) is the only intervention demonstrated to reduce the incidence of dementia and mild cognitive impairment.

Although screening for cognitive impairment is not recommended, detection can lead to identification of treatable conditions (e.g., medication side effects, depression, or hearing impairment). Symptoms of cognitive decline, such as forgetfulness, disorientation, and changes in personality, require cognitive testing. Disorientation to year is about 85% sensitive and 95% specific for cognitive impairment. The Mini-Cog test (Table 361-5), also has high sensitivity and specificity.

Decision-making capacity is specific to each decision. Patients are competent when they can do all of the following:

- Make and express personal preferences.
- Comprehend the risks and benefits of the intervention.
- Comprehend the implications of the decision.
- Give rational reasons for the decision.

If the patient is not competent, the decision should be made by a surrogate or, if a surrogate is not available, by the physician, as specified by state law (Chapter 2).

MOOD AND AFFECT

Universal screening is recommended to assess mood and affect.[2] A positive answer to either of these two questions has a 95% sensitivity and 65% specificity for a major depressive disorder:

1. During the past month, have you often been bothered by feeling down, depressed, or hopeless?
2. During the past month, have you often been bothered by little interest or pleasure in doing things?

All patients should be screened once and also after major life events, such as retirement or a serious illness, and whenever the clinician senses sadness or aversion on seeing a patient.

VISION

Impaired visual acuity is associated with worse functional status, worse quality of life, falls, depression, and social isolation. The prevalence of impaired visual acuity with refractive correction increases from 1% at age 65 years to nearly 20% in persons aged 80 years or older.

Although screening has not been recommended for older adults,[A6] it is useful for the clinician to ask a simple question: whether the patient has difficulty driving, watching television or reading, or doing any of their daily activities because of their eyesight, even while wearing eyeglasses. Impaired visual acuity is determined using the Snellen eye chart (E-Fig. 391-1) as worse than 20/40; 20/200 is the legal threshold for blindness.

HEARING

Hearing loss (Chapter 396) is common, often unrecognized and untreated, and associated with social isolation, functional decline, depressive symptoms, and cognitive impairment. Presbycusis initially affects high frequencies and often-associated central auditory processing disorders can further decrease the ability to understand words over background noise. Routine screening for hearing loss is not recommended,[3] but hearing tests are warranted when the patient, the caregiver, or the physician visit reveals a potential loss of hearing because amplification with a hearing aid, cochlear implant, or assisted listening device can be very helpful.[4]

To detect hearing loss, the clinician can ask, "Do you feel you have hearing loss or have any difficulty hearing?" The whisper test has high sensitivity and specificity: the clinician stands 2 feet behind the patient, occludes one ear, rubs the tragus, whispers a combination of 6 numbers and letters, and then asks the patient to repeat the sequence. The whisper test is positive if fewer than 3 numbers and letters are repeated correctly. Hearing loss also can be detected by a handheld otoscope with a built-in audiometer and by tests on personal computers and smartphones.

When hearing loss is detected, the patient's companion can be asked about its severity and effects on functioning. When hearing is diminished, it is important to examine the ear. If substantial cerumen is found, it must be removed, sometimes by a specialist, and then the hearing evaluation can be performed again.

NUTRITION

The patient should be asked whether a change in weight has occurred over the last year and whether any change was intentional. Weight should be measured and the body mass index (BMI) calculated in kg/m^2 (Chapter 201): BMI of less than 18.5 is underweight, 18.5 to 24.9 is normal, 25 to 29.9 is overweight, 30 to 39.9 is obese, and 40.0+ is severely obese.

Obesity (Chapter 201) affects more than 40% of older Americans and is associated with poorer function and mobility, many chronic diseases, and decreased life expectancy. Obesity and its adverse effects are ameliorated by intensive, multicomponent interventions that may include bariatric surgery.

Unintentional weight loss (Chapter 118) of 5% or more is associated with increased mortality and should prompt evaluation for an underlying cause of malnutrition (Chapter 198), including depression, dementia, dental disease, cancer, malabsorption, poverty, and neglect. Protein and energy supplementation (Chapter 198) increase survival in hospitalized patients who are undernourished on admission. Screening for deficiency of vitamin D or B_{12} is not recommended because of insufficient evidence.[5]

MOBILITY AND LIFE SPACE

Mobility without the assistance of another person depends on the environment and assistive devices. For example, a person may walk the aisles of a grocery store with a shopping cart but be unable to walk across a parking lot without assistance. Life-space mobility, which is the distance through which a person moves over a month, varies from being restricted to a room to traveling outside the region.

Gait speed predicts survival, although less in the very old: for example, 65 year-old men with gait speeds of 1.6 meter (m) per second (s) and 0.8 m/second have median survivals of 32 years and 15 years, respectively; 90-year-old men with gait speeds of 1.6 m/second and 0.8 m/second have median survivals of 8 years and 6 years, respectively. Gait speed also predicts survival in women, and survival in women is generally 20% or more longer than in men of the same age and gait speed.

Mobility can be assessed with two questions:

1. For health or physical reasons, do you have difficulty climbing up 10 steps? Walking ¼ mile?
2. Because of underlying health or physical reasons, have you modified how you climb 10 steps or how frequently? Walk ¼ mile?

The clinician should then evaluate risk factors for impaired mobility, including low physical activity, obesity, symptoms that limit mobility, and chronic diseases that cause organ failure. By observing how the patient arises from a chair, the patient's gait, and the strength of major muscle groups, the clinician can assess the likely causes of poor mobility and whether they may be amenable to physical therapy or other interventions.

RISK OF FALLS

Poor balance is associated with high all-cause mortality,[6] and falls (Chapter 24), which are the 11th most frequent cause of death among people ages 75 years or older, kill almost as many people as prostate cancer and breast cancer combined. One third of community-dwelling persons older than age 65 years fall each year, and the risk increases with age.

On an annual basis, patients should be asked: "Have you fallen in the last year?, Are you afraid of falling?" If the answer to either question is yes, the clinician could measure orthostatic blood pressure, determine nutritional status, assess visual acuity, and examine the feet and knees (for causes of mobility impairment), the strength of the legs and arms, sensation and proprioception of the feet, balance, gait, and cognition. The Timed Up and Go approach measures how long it takes a person to stand up from a chair, walk 10 feet, turn, return, and sit down again; if the sequence requires more than 12 seconds or reveals any gait abnormalities, the patient is at increased risk for falls.[7]

When possible, any medications that affect balance, alertness, or judgement should be discontinued. Older people at increased risk for falls benefit from exercise programs.[A7]

CONTINENCE

Incontinence of urine (Chapter 115) or stool (Chapter 131) and urinary tract symptoms decrease quality of life, limit social function and life space, and can lead to falls and admission to long-term care facilities. Urinary incontinence, which occurs in one third of older women, usually improves with specific interventions, often without medication or surgery.[A8,A9] Three quarters of older men experience urinary frequency, nocturia, or urgency, almost always related to prostate conditions (Chapter 115). Fecal incontinence with at least monthly loss of stool occurs in 8% of men and women aged 50 years and older.

Every elderly patient should be asked: "Have you had urinary incontinence to the extent that it is bothersome?" Further questions determine the frequency and severity of the symptoms and often the pattern (overflow, urge, stress, or mixed incontinence; Chapter 115).

FRAILTY

Frailty (Table 24-1) is global decline in physical function associated with unintentional weight loss of 10 pounds in the last year, self-reported exhaustion, low physical activity, weak grip strength, and slow walking speed.[8] The presence of three or more of these characteristics predicts a five-fold increase in mortality as well as hip fractures, cognitive decline, and adverse outcomes of surgery and hospital care.

SEXUALITY

Among older people in excellent or very good health, nearly 80% of individuals ages 66 to 75 years old and nearly 40% of individuals ages 76 to 85 years old are sexually active. Sexual activity is associated with better cardiovascular health, greater self-esteem, and higher life enjoyment.[9] Nonetheless, sexual problems are common, and sexually transmitted infections have increased in older adults.

Each elderly patient should be asked: "Do you have sex?" The risk for sexually transmitted infections should be assessed (Chapter 264), with behavioral counseling for patients who are at risk.

SELF-NEGLECT AND ABUSE

More than 10% of older people suffer mistreatment, which includes emotional, financial, physical, and sexual abuse, as well as self-neglect and neglect by others. Self-neglect is most common, especially among persons ages 75 years or older and individuals with lower socioeconomic status, cognitive impairment, or physical disability.

To identify difficulties that can lead to self-neglect, patients should be asked how they manage their daily lives: "Are you afraid of anyone?, Has anybody hurt you?, Is anyone taking or using your money without your permission?" Family caregivers should be asked: "Are your elder's needs more than you are able to handle? Are you worried that you might hit your elder? Have you hit your elder?"

Most states have laws that require clinicians to report a reasonable suspicion of abuse or self-neglect to adult protective services.

MEDICATION REVIEW

Polypharmacy is common and can cause drug-drug interactions as well as other adverse effects such as nonadherence. The patient and caregiver should be asked to bring all prescribed and over-the-counter medicines to each visit. The physician should record all the medications and determine which may lead to drug-drug interactions or potentially have harms that exceed their benefits; commercially available drug interaction programs are useful (e.g., Drug Interactions Checker for Drugs, Food and Alcohol: https://www.drugs.com/drug_interactions.html). Drug safety can be improved by goal-directed programs and by explicit deprescribing, which is the process of withdrawing medications, usually one at a time under the supervision of a health professional, with the goal of improving outcomes and minimizing potential harms of polypharmacy.[10,11]

THE BUILT AND SOCIAL ENVIRONMENTS

BUILT ENVIRONMENT

The ability of an older person to live safely as they wish depends on how their home environment and community fit their abilities and needs. Inability to access needed services can lead to self-neglect. Decisions about the appropriateness of the home environment often involve a tension between safety and autonomy. This determination can be based on two questions:

1. Is the home safe, given the patient's cognitive and functional abilities?
2. Can the patient access needed community services, such as stores and a bank?

Home safety to reduce risk for falls can be assessed by a home health agency or by the patient using a brochure from the Centers for Disease Control and Prevention (CDC). (Check for Safety: A Home Fall Prevention Checklist for Older Adults: https://www.cdc.gov/steadi/pdf/check_for_safety_brochure-a.pdf).

SOCIAL SUPPORT

Older persons with loss of independence of ADLs or instrumental ADLs usually require help with important decisions and with daily activities. Informal (i.e., unpaid) support from family and friends is an important source of help,[12] but the clinician should also determine who is available to help the patient and who has durable power of attorney for health care and finances.

FINANCIAL ASSESSMENT

Insufficient money to pay for food, housing, and medical care increases the risk for functional decline and death. If financial security is in doubt, the patient should be asked: "Do you have enough money to pay for groceries? Bills? Medication? Medical/dental bills? A small emergency? A major emergency?" The answers can guide further questions as to whether the patient is a beneficiary of Medicare or Medicaid, is a veteran, or has private health or long-term care insurance. For example, insurance or veterans' benefits can pay for home assistance and daycare.

PROGNOSIS

Prediction of functional status, ability to live independently, and survival inform planning and decisions by older persons and their families. Life expectancy, which is the median length of survival for a group of people, varies according to age, gender, and race (E-Table 23-1 and https://www.cdc.gov/nchs/data/nvsr/nvsr69/nvsr69-12-508.pdf). Life expectancy can be estimated more precisely by incorporating clinical characteristics with online calculators (e.g., see https://eprognosis.ucsf.edu/calculators/). For example, just a few criteria such as male sex (1 point), dependent ADL (2 points for 1 to 4 ADLs and 5 points for 5 dependent ADLs), and 4 clinical characteristics (heart failure, 2 points; serum creatinine >3 mg/dL, 2 points; albumin level 3.0 to 3.4 g/dL or <3.0 g/dL, 1 or 2 points, respectively; nonmetastatic or metastatic cancer, 3 or 8 points, respectively) can classify hospitalized older adults into groups with median 1-year mortality rates of 4% (0 or 1 point), 19% (2 or 3 points), 34% (4 to 6 points), and 64% (>6 points), respectively.

For treatments and screening tests, it is important to determine whether the "time to benefit" (how long it will take for the long-term benefit to exceed the short-term risk) exceeds the life expectancy.[13] For example, an intervention for which benefit exceeds harm after 5 to 10 years (e.g., cancer screening) is unlikely to benefit a person with a life expectancy of 3 years.

GOALS AND PREFERENCES

Life goals often change over time, and advance care planning unfortunately does not necessarily improve end-of-life care.[14] Each year and after major

life events, a patient should be asked questions such as: "As you look to the future, what is important to you?," and "What can I do for you today and over the coming months?" Goals may include long-term survival, survival to an event in the foreseeable future, living at home, maintenance of a role, or control of symptoms (e.g., pain or dyspnea). Clinicians can suggest what goals are achievable, what actions can achieve specific goals, and the risks of actions and their possible consequences. Symptom-focused management can improve survival.[A10]

PREVENTIVE SERVICES

Preventive services that benefit older people include vaccinations, screening tests for selected asymptomatic diseases, and behavioral counseling. Vaccinations recommended by the CDC for older adults (Chapter 15) are annual inactivated or recombinant influenza vaccination, two one-time pneumococcal vaccinations (PCV13 and PPSV23 administered 1 year apart), herpes zoster recombinant vaccination (two doses of RZV), and tetanus-diphtheria (Td) or tetanus-diphtheria-pertussis (Tdap) vaccination every 10 years.

Preventive services for which current evidence demonstrates net benefit are recommended by U.S. Preventive Services Task Force for older adults (Chapter 12; http://epss.ahrq.gov/ePSS/search.jsp). Screening is recommended for colorectal cancer and breast cancer to age 75 years and for lung cancer in past or current smokers up to age 80 years. Other recommendations (E-Table 23-2) pertain to screening for hypertension (Chapter 64), abdominal aortic aneurysm (Chapter 63), prediabetes or diabetes (Chapter 210), osteoporosis (Chapter 225), depression (Chapter 362), unhealthy use of alcohol or drugs (Chapters 364 and 365), and certain infections (e.g., human immunodeficiency virus, syphilis, gonorrhea and chlamydia, hepatitis B, hepatitis C, and latent tuberculosis). Aspirin for primary prevention is not recommended in adults ages 60 years or older.[A11]

GERIATRIC ASSESSMENT IN PRACTICE

Geriatric assessment asks questions that can be completed by the patient, caregiver, or office staff, as well as by clinicians (a physician, advanced practice nurse, social worker, and/or physical therapist). Tests can be completed by office staff or a clinician (Table 23-1). Geriatric assessment identifies syndromes, impairments, and disabilities that require a targeted plan to guide management by the principal physician or other clinician over time.

Geriatric assessment is especially useful in hospitalized older adults, but it is reasonable to perform it annually in individuals over age 75 years, patients with multiple chronic diseases, and patients who have survived after major illnesses. Many elements of geriatric assessment are included in Medicare's Initial Preventive Physical Exam and the Annual Wellness Visit (see Medicare Wellness Visits – ICN MLN6775421 February 2021 [https://www.cms.gov] for covered services).

E-TABLE 23-2 ALL PREVENTIVE SERVICES RECOMMENDED BY THE UNITED STATES PREVENTIVE SERVICES TASK FORCE FOR OLDER ADULTS, ACCORDING TO THE GRADE OF RECOMMENDATION

RECOMMENDED PREVENTIVE SERVICE*	GROUP OF OLDER ADULTS	GRADE OF RECOMMENDATION†
Colorectal Cancer Screening	Adults aged 50-75 years Selected adults aged 76-85 years	A C
Hypertension Screening	All adults	A
Tobacco Smoking Cessation	All adults	A
Syphilis Infection Screening	Adults at increased risk for infection	A
Chlamydia and Gonorrhea Screening	All women at increased risk for infection	B
Pre-diabetes and Type 2 Diabetes Screening	Adults aged 70 years or younger who have overweight or diabetes	B
Lung Cancer Screening	Adults aged 50-80 years with a 20 pack-year history who smoked within the past 15 years	B
Hepatitis B Virus Infection Screening	Adults at increased risk of infection	B
Healthy Diet & Physical Activity	Adults with cardiovascular disease risk factors	B
Sexually Transmitted Infections Counseling	Adults at increased risk for sexually transmitted infections	B
Unhealthy Drug Use Screening	All adults	B
Hepatitis C Infection Screening	Adults aged <80 years	B
Abdominal Aortic Aneurysm Screening	Men aged 65-75 years who have ever smoked Selected men aged 65-75 years who have never smoked	B C
Medicines to Reduce Risk for Breast Cancer	Women at increased risk for breast cancer aged 35 years or older	B
BRCA-Related Cancer Assessment & Counseling	Women with a personal or family history of breast, ovarian, tubal, or peritoneal cancer or an ancestry associated with *BRCA1/2* gene mutation	B
Unhealthy Alcohol Use Screening, Interventions	All adults	B
Weight Loss to Prevent Obesity-related Events	Adults with a body mass index of ≥30	B
Osteoporosis Screening	Women aged 65 years and older	B
Fall Prevention Interventions	Community-dwelling adults aged 65 years or older	B
Statin Use	Adults aged 40-75 years with no cardiovascular risk factors, ≥1 CVD risk factor, and a 10-year CVD event risk ≥10% Adults aged 40-75 years with no cardiovascular risk factors, ≥1 CVD risk factor, and a 10-year CVD event risk 7.5–10%	B C
Latent Tuberculosis Infection Screening	Adults at increased risk for infection	B
Depression Screening	All adults	B
Breast Cancer Screening	Women aged 50-74 years	B
Prostate Cancer Screening	Men aged 55-69 years	C
Skin Cancer Prevention	Adults with fair skin types	C
Healthful Diet and Physical Activity	Adults without obesity or cardiovascular disease risk factors	C

*Several preventive services are not recommended for older adults because there is evidence that the service does not have net benefit or because there is insufficient evidence of net benefit. Evidence is insufficient to recommend screening for the following: impaired visual acuity, primary open-angle glaucoma, atrial fibrillation, vitamin D deficiency, hearing loss, cognitive impairment, abdominal aortic aneurysms in women, abuse or neglect, obstructive sleep apnea, skin cancer, thyroid dysfunction, suicide risk, oral cancer, and bladder cancer. Screening for the following is not recommended because of evidence of lack of net benefit: COPD, carotid artery stenosis, asymptomatic bacteriuria in older adults, pancreatic cancer, ovarian cancer, and testicular cancer.

†Grade of Recommendation: A = there is high certainty that the net benefit is substantial. B = there is high certainty that the net benefit is moderate or there is moderate certainty that the net benefit is moderate to substantial. C = there is at least moderate certainty that the net benefit is small.

24 COMMON CLINICAL SEQUELAE OF AGING

JEREMY D. WALSTON

EPIDEMIOLOGY

Older adults make up the majority of patients actively treated in the health care system, in large part owing to their increased burden of chronic diseases but also because of their marked vulnerability to adverse health outcomes, such as functional and cognitive decline (Chapter 361), falls, delirium (Chapter 361), and frailty. This age-related vulnerability is thought to have its basis in altered biology that results in tissue and physiologic system changes, which in turn may contribute to many of these conditions and to the chronic disease states commonly seen in older adults. Importantly, these biologic changes are likely to be heterogeneous and to occur at different chronologic ages and in different organs at different rates (Fig. 24-1). These complex age-related biologic changes represent a source of vulnerability that sets the stage for the marked increase in clinical sequelae observed in older adults.

PATHOBIOLOGY

Age-Related Cellular and Molecular Changes

The multiple biologic changes of aging affect important homeostatic functions and can lead to altered cellular function, declines in tissue resiliency, and cellular dropout. Although the exact contributions of each of these biologic changes are not yet known, improvements in precision medicine approaches may facilitate future targeted prevention and treatment strategies. For example, autophagy, an intracellular process responsible for the recycling of damaged or redundant organelles or proteins, becomes less effective with aging.[1] The result is an intracellular accumulation of dysfunctional mitochondria and proteins, which in turn can trigger cellular dysregulation through increased levels of free radicals, lower mitochondrial energy production, and programmed cell death or apoptosis. Senescent cell populations arise with increasing age and lead to alterations in tissue and immune system function.[2] For example, some fibroblasts and fat cells evolve toward a senescent cell phenotype whereby reproduction and cell death are less likely to take place and survival persists in an altered, less functional state. These senescent cells secrete inflammatory cytokines and other bioactive molecules that pathologically alter surrounding tissues. Senescent T-cell populations also evolve with increasing age, perhaps related to early-life viral infections. Senescent T cells are less able to respond appropriately to immunogenic signals, thereby increasing vulnerability to infections. Another biologic age-related change is an increasing tendency for apoptosis, or programmed cell death. Although apoptosis is a normal cellular program that kills and disassembles damaged or redundant cells in all tissues, it accelerates with age and likely contributes to the vulnerability to chronic disease states, such as Parkinson disease (Chapter 378), heart failure (Chapter 45), and the generalized loss of cell number in many tissues. Finally, evidence suggests that increased activity in transforming growth factor-β signaling may play an important role in the fibrotic changes that are observed in the heart, skeletal muscle, and lung tissue and that result in functional decrements with increasing age. Importantly, these aging-related molecular and cellular changes are heterogeneous and may affect individuals at different ages and in different tissues. However, the end results are increased susceptibility to chronic disease states, frailty, declines in function and cognition, and ultimately mortality.

Physiologic System Dysregulation and Its Consequences

Dysfunction in multiple physiologic stress response systems also plays a role in late-life vulnerability. Chronic diseases such as diabetes, vascular disease, chronic obstructive pulmonary disease, depression, and heart failure activate the innate immune system, the sympathetic nervous system, and the hypothalamic-pituitary-adrenal axis, which in turn increases the production of cortisol and the inflammatory cytokine interleukin-6 (IL-6). These responses further exacerbate aging-related clinical conditions, such as osteoporosis and hypertension, and increase vulnerability to frailty, functional decline, accidental injury, and worsening chronic disease states (E-Fig. 24-1).

CLINICAL MANIFESTATIONS

Some clinical manifestations are related not to physiologic aging but rather to cumulative exposures, such as with sun-related skin cancer (Chapter 188), or the delayed expression of genetic abnormalities, such as Huntington disease (Chapter 379) or polycystic kidney disease (Chapter 112). However, many organs and systems become less functional with age. For example, a healthy 70-year-old will have only about 50% of the lung function (Chapter 71) and renal function (Chapter 101) of a young adult. The resultant lack of physiologic reserve capacity does not affect day-to-day function but can greatly affect the ability to recover from a severe illness that exhausts the body's reserve capacity.

Despite normal baseline temperatures, older adults are more susceptible to hypothermia or hyperthermia (Chapter 95) after environmental exposure, even though they are less likely to develop fever with infections. For example, patients with pneumonia (Chapter 85) may present with confusion and dehydration rather than with fever and cough. Among older persons with critical illness, more than half die within 1 month or experience significant functional decline over the following year.

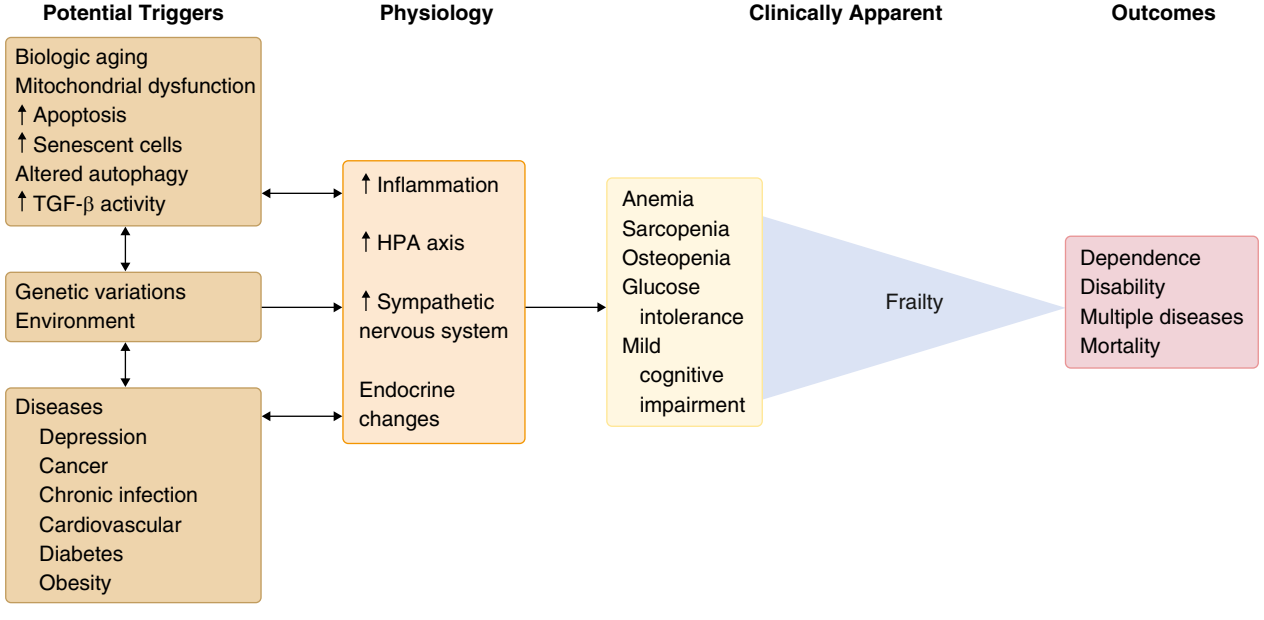

FIGURE 24-1. **Comprehensive model pathway for biologic vulnerability to adverse outcomes in aging.** HPA = hypothalamic-pituitary-adrenal; TGF-β = transforming growth factor-β.

ABSTRACT

Older adults comprise the majority of medical patients and have many more iatrogenic complications compared with younger adults. Complex physiologic and biologic aging-related changes, as well as chronic disease states, contribute to this vulnerability. Common organ- and tissue-specific age-related changes contribute to cardiovascular disease, urinary tract conditions, and musculoskeletal changes. Many of these changes contribute to frailty and to related late-life vulnerability to adverse health outcomes and mortality.

EFFECTS OF AGING ON SPECIFIC ORGANS AND SYSTEMS

CARDIOVASCULAR SYSTEM

Between the ages of 20 and 80 years, left ventricular systolic function does not change, but the left ventricle gradually thickens. The result is that left ventricular filling in early diastole declines by 50%, and ventricular filling becomes more dependent on atrial contraction (Chapter 41).[3] Although atherosclerosis is the most important cause of symptomatic cardiac disease in elderly people, the age-associated vascular stiffness results in an age-related increase in heart failure despite normal systolic function (Chapter 45). With the gradual loss of up to 90% of sinus node pacemaker cells by the age of 80 years, both the resting heart rate and the maximal heart rate with exercise decline. Conduction system dysfunction contributes to an increase in the prevalence of atrial fibrillation, which is seen in about 4% of community-dwelling older individuals (Chapter 52) and can develop in up to one third of the elderly after surgery (Chapter 401). Heart valves thicken and stiffen, and the prevalence of aortic stenosis and mitral annular calcifications rises (Chapter 60), often causing heart murmurs.

Stiffening of the aorta causes an increase in systolic blood pressure, whereas diastolic blood pressure often stays stable or even declines (Chapter 64). Hypertensive patients age 80 years and older should generally be treated according to current recommendations for people older than 65 years, with a systolic blood pressure goal of less than 120 mm Hg likely associated with lower cardiovascular and all-cause mortality for otherwise healthy older adults.[A1,A2] However, some older adults, especially frail elders, may not tolerate systolic blood pressures this low without side effects, so treatment must be individualized. For some patients over age 80 years, a modest reduction in their multidrug regimen may sustain target blood pressure levels with fewer side effects.[A3] Blood pressure control reduces the incidence of cognitive impairment and dementia (Chapter 371) in older persons with mild cognitive deficits,[A4] and discontinuation of antihypertensive treatment does not improve cognitive, psychological, or general daily functioning.[A5] There is little evidence, however, of the impact of maintaining a lower blood pressure on those who are over age 90 years.

The combination of impaired ventricular filling and the inability to increase the heart rate with stress contributes to the postural hypotension that is seen in 20% of older individuals (Chapter 49), as well as their predisposition to falls and syncope with stresses that younger individuals would tolerate. The reduced ability of the elderly to tolerate cardiovascular stress must be recognized and anticipated whenever they experience a major illness. In addition, coronary artery disease can limit cardiac reserve and increase the risk that hypotension will cause a secondary myocardial infarction.

Hyperlipidemia is common in older adults, and statins are effective in this age group for reducing coronary heart disease events.[A6,A7] However, their favorable cost-effectiveness for primary prevention in persons over age 75 years can be offset by even minor geriatric-specific side effects, and these drugs can be discontinued safely in the setting of advanced, life-limiting illness.[A8] Low-dose aspirin is not beneficial in healthy elderly people because its side effects outweigh its benefits.[A9,A10] However, low-dose edoxaban (15 mg daily) may be a safe and effective option to prevent systemic embolization in elderly patients who otherwise seem not to be safe candidates for anticoagulation.[A11]

All adult cardiac conditions become more common with aging. Exercise training can improve endurance and decrease age-related cardiac stiffness.[A12] Treatment recommendations for specific cardiac abnormalities must balance the potential benefit of targeted interventions against the common multimorbidities seen with aging.[4]

RESPIRATORY SYSTEM

The chest wall stiffens with advancing age, and the lungs lose elastic recoil (Chapter 73).[5] Maximal vital capacity declines by about 40%, but oxygen exchange declines by about 50% because of the additive effect of progressive ventilation-perfusion mismatching (Chapter 73). As a result, the arterial Po_2 of many 80-year-olds is about 70 to 75 mm Hg. The clinical manifestations are often progressive shortness of breath with exercise (Chapter 71) and an increased susceptibility to community-acquired pneumonia (Chapter 85) and even to aspiration pneumonia.

GASTROINTESTINAL SYSTEM

Taste and smell (Chapter 395) decline with advancing age. Food tends to taste less sweet and more bitter.

The esophageal sphincter can become lax (Chapter 124), thereby increasing reflux and even aspiration. Atrophic gastritis reduces the risk of duodenal ulcer but also the absorption of iron (Chapter 145) and vitamin B_{12} (Chapter 150). Delayed gastric emptying can lead to a sense of early satiety and decreased appetite.

A gradual decline in the number of hepatocytes decreases the weight of the liver by about one third by the age of 90 years and decreases the liver's ability to metabolize drugs (Chapter 25). Distal colonic motility from the rectosigmoid to the anal canal declines, and more than 60% of elderly individuals develop constipation (Chapter 122). Diverticula (Chapter 128) become more common with age and are seen in up to 50% of people older than age 80 years.

URINARY SYSTEM

Glomerular filtration declines by about 1% per year, and kidney size declines by about one third in older adults (Chapter 101). Maximal concentrating capacity declines, and it becomes more difficult to excrete a salt load or to conserve water in the face of dehydration.

The bladder becomes more irritable with advancing age and may generate less power, which is especially a problem in men with prostatic hypertrophy (Chapter 114). By comparison, urinary incontinence (Chapter 115) is more prevalent in women. Residual bladder urine volume increases, and nocturia is common. Vaginal and urethral atrophy predispose women to urinary tract infections (Chapter 263).

The kidney is more susceptible to the effects of medications, particularly nonsteroidal anti-inflammatory drugs, which can result in sodium and fluid retention and subsequent hypertension. In elderly individuals, a slight acidemia results from impaired acid excretion and may contribute to the development of osteoporosis.

ENDOCRINE SYSTEM

Growth hormone levels fall with advancing age (Chapter 205), thereby resulting in decreased muscle strength, thinning of bones and skin, and increased central fat. However, growth hormone replacement does not appear to result in improved muscle strength. Levels of thyroid hormones do not decline with age (Chapter 207). Parathyroid hormone levels, however, commonly increase, especially in women, probably in response to the kidney's declining ability to maintain normal serum levels of phosphorus and calcium (Chapters 184 and 227).

The ability of the pancreas to release insulin is blunted with advancing age (Chapter 210), but the kidney's clearance of insulin also decreases. The net result is maintained plasma insulin levels in the fasting state but an increased likelihood of postprandial or stress-induced hyperglycemia. Dramatic declines in estrogen and progesterone production precipitate menopause at an average age of 51 years (Chapter 222). Testosterone levels begin to decrease in men by about 50 years of age, often with resulting declines in sexual function but not in the potency of semen (Chapter 216). Testosterone supplements reverse the muscle loss and sexual implications of declining testosterone levels, but their safety and effect on the risk of cardiovascular complications are uncertain.[6,7]

IMMUNE SYSTEM

Declines in the responsiveness of the immune system explain why the incidence of autoimmune conditions, such as systemic lupus erythematosus (Chapter 245) and multiple sclerosis (Chapter 380), declines in the elderly. However, this same decline explains increased morbidity and mortality with infectious diseases and the increased risk of reactivating infections such as tuberculosis (Chapter 299) and herpes zoster (Chapter 346). These risks emphasize the importance of vaccination against herpes zoster, influenza, pneumococcal pneumonia, and tetanus in the elderly (Chapter 15).

HEMATOPOIETIC SYSTEM

Hematopoiesis (Chapter 142) is generally sustained with aging, except in response to marked stress and inflammatory pathway activation. The one exception is that the hematocrit declines somewhat in older men, presumably owing to their lower testosterone levels. Clonal hematopoiesis, which is the proliferation of a single cell, is more common with aging and increases the risk of cancer, cardiovascular disease, and all-cause mortality.[8]

INTEGUMENTARY SYSTEM

With aging, the epidermis and dermis adhere less tightly and the subcutaneous tissue thins, thereby making the skin feel looser and more likely to wrinkle and ulcerate. Clinical sequelae include senile purpura (Fig. 24-2) as tears in small venules after bumps or abrasions (Chapter 407). Ultraviolet light exposure also predisposes to skin cancer (Chapter 188), rosacea (Chapter 406), xerosis, and hair loss (Chapter 409). Wound healing is also compromised, and complete skin healing can take 5.5 weeks instead of 3.5 weeks in individuals older than age 65 years.

FIGURE 24-2. Senile purpura is a common and benign condition that results from impaired collagen production and capillary fragility in some older adults. In the absence of other signs of disease, no investigation is necessary. (From Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine*. 3rd ed. London: Mosby; 2003.)

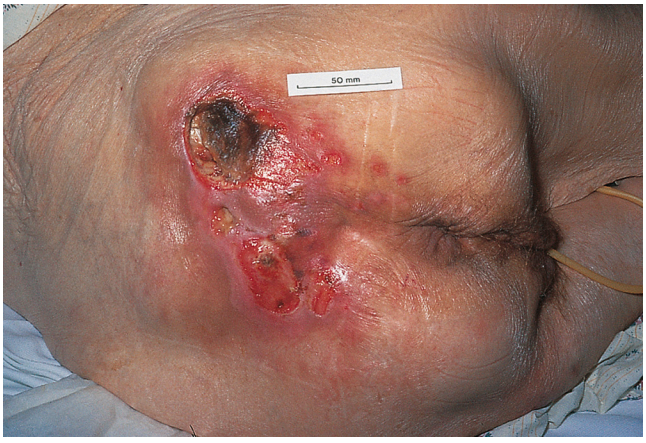

FIGURE 24-3. Severe sacral pressure sore, one of the serious but preventable complications of immobility. (From Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine*. 3rd ed. London: Mosby; 2003.)

Pressure Sores

Older adults are more prone to pressure sores when they are bedridden. Pressure sores, which are necrotic areas of muscle, subcutaneous fat, and skin, usually occur between underlying bone and a hard surface (or a soft surface during a prolonged time) as a result of compression and subsequent ischemia (Fig. 24-3). A continuous-pressure threshold of only 30 to 35 mm Hg is needed to cause pressure sores, and a standard mattress can generate pressures five times as high. In addition to pressure injury, other contributing factors include shear injury from rubbing constantly against underlying surfaces, burning injury from friction of the superficial skin layers, and moisture that softens the skin, makes it stick to underlying surfaces, and provides easy access for infection.

TREATMENT AND PREVENTION

Safe positioning, regular turning, avoidance of direct pressure, pressure-reducing beds, and advanced static mattresses or advanced static overlays can reduce the incidence of pressure sores. Alternating air mattresses or overlays are not recommended.[9] Pressure sores should be photographed to establish a baseline. The wound should be freed of any pressure to prevent additional pressure ulcers. Wet-to-dry dressings are a mainstay, and semiocclusive and occlusive dressings also can be helpful. Protein or amino acid supplementation enriched with zinc and antioxidants,[A13] hydrocolloid or foam dressings, and adjunctive electrical stimulation may be useful. Surgical or chemical débridement is often required. Topical or systemic antibiotics (Chapter 261) may be needed. Pressure ulcers usually heal within 6 months, but surgical repair is sometimes required.

MUSCULOSKELETAL SYSTEM

Bone mass and density decrease by about 1% per year but by up to 2 to 3% per year in the first 5 to 10 years after menopause in women (Chapters 222 and 225). In older women with osteopenia, bisphosphonate therapy (e.g., zoledronate, four 5-mg infusions at 18-month intervals)[A14] significantly reduces the risk of nonvertebral or vertebral fractures within 1 year[A15] and therefore is useful in women with a life expectancy longer than 1 year. Tendons and ligaments become less elastic, thereby contributing to a higher incidence of rupture, especially of the Achilles tendon. Sarcopenia is common in older adults.[10] For example, muscle mass declines by about 25% by the age of 70 years and by 30 to 40% by the age of 80 years unless it is offset by exercise.

CLINICAL PHARMACOLOGY

Older adults take a disproportionate share of all prescription (Chapter 25) and nonprescription (Chapter 30) medications, and they are at increased risk of drug-drug interactions. Because older adults have less muscle mass and more fat as a proportion of total body weight, they are more sensitive to the effects of water-soluble drugs and have prolonged effects from lipophilic drugs. Declines in renal and hepatic function reduce the clearance of most drugs, although drugs that are conjugated and glucuronidated are cleared relatively normally. Older people also are more likely to be nonadherent to prescribed regimens owing to the number of medications and their cost, mental impairment, and medication side effects.

SENSORY AND SLEEP

In addition to age-related cognitive decline (Chapters 361 and 361), hearing loss develops in about 25% of individuals older than 65 years (Chapter 396), with decreased neural transmission leading to difficulty in discriminating important sounds from background noise. Presbycusis diminishes the ability to hear high-frequency sounds.

The thickening and stiffening of the lens diminish the ability to focus on nearby objects and increase glare (Chapter 391). Transmission of light through the lens may decline by 50% or more, so elderly individuals require more ambient light. Vitreal detachment causes floaters that also can interfere with vision. Decreased tear production causes dryness of the eyes. All of these conditions contribute to a decline in visual acuity to the extent that 40% of men and 60% of women older than 65 years have a visual acuity of 20/70 or worse.

Older adults tend to have difficulty in sleeping (Chapter 374) yet spend much more time in bed. Sleep apnea also becomes more common with advancing age (Chapter 374).

FRAILTY

EPIDEMIOLOGY

Frailty in older adults is a geriatric syndrome of weakness, slowness, and weight loss, owing to an aggregate of comorbid conditions. Frailty serves as a clinical indicator of which older adults are at high risk for adverse outcomes, including delirium (Chapter 361), falls, and mortality.[11,12] Measures of frailty are also increasingly utilized to identify older adults who are at highest risk for adverse health outcomes related to procedures or medical treatments, including intensive care,[13] general surgery,[14] hip fracture surgery,[15] or coronavirus disease 2019 (COVID-19) infection.[16]

PATHOBIOLOGY

The biology that differentiates vulnerable or frail older adults from resilient or robust older adults is complex and multisystemic in nature. For example, diminished heart rate variability, which is a marker of dysregulated sympathetic nervous system activity, is associated with aging, frailty, and cardiac arrhythmias. Frail older adults have significantly higher levels of salivary cortisol during the afternoon nadir period, thereby suggesting chronically increased activity of the hypothalamic-pituitary-adrenal axis. Elevated levels of inflammatory cytokines, especially IL-6, tumor necrosis factor-α receptor 1 (TNFR1), and C-reactive protein, are strongly related to functional decline, frailty, chronic disease, and mortality in older adults, probably owing to increased fat, more senescent cells, and free radical production from altered mitochondria. IL-6 is likely to have a negative impact on stem cells and satellite cells, which in turn may contribute to the chronic anemia and age-related declines in skeletal muscle (sarcopenia) and bone mass (osteopenia) commonly observed in frail, older adults. TNFR1 stimulates apoptosis and necroptosis, which are cell programs that lead to cell death and possibly tissue depletion and vulnerability later in life. In addition to stress response systems, endocrine factors that normally maintain muscle mass play a role in frailty. For example, the adrenal androgen dehydroepiandrosterone sulfate and insulin-like growth

factor 1 are significantly lower in frail adults. Future preventive or treatment strategies to reduce frailty and improve resiliency may target some of these stress responses or endocrinologic changes.

CLINICAL MANIFESTATION AND DIAGNOSIS

Validated frailty screening tools (Table 24-1) enable physicians to identify patients at highest risk of side effects, adverse outcomes, and mortality and to develop preventive interventions that will decrease risk and improve quality of life. One approach is to measure physiologic parameters such as grip strength, walking speed, and weight loss, as well as to gather information about activity and fatigue levels. With use of this approach, the prevalence of frailty rises with increasing age; approximately 10% of community-dwelling adults older than 65 years meet these frailty criteria and subsequently are at increased risk of functional decline, falling, hospitalization, and death, even after adjustment for age, socioeconomic and smoking status, and multiple common disease states.

TREATMENT AND PREVENTION

Interventions should be targeted to the specific characteristics of a patient's frailty. Increasing physical exercise is the mainstay of most programs.[A16] Focused prevention of iatrogenic injuries or recurrent hospitalizations and remediation of symptoms are often warranted for frail vulnerable older adults (Fig. 24-4). Physical activity, exercise interventions, and nutritional supplementation can reduce disability and symptoms and improve quality of life across the spectrum of robust to frail older adults. In addition, exercise and weight loss together improve function in obese and frail older adults. Other options include a team-based approach that engages the patient, family members, caregivers, health care providers, and social workers. Classic palliative care (Chapter 3), with appropriate pain management, less invasive treatment plans, limited hospital visits, and organized home care plans, can greatly improve quality of life. If the patient has frequently been admitted to an inpatient setting, a program for all-inclusive care or a medical daycare setting may help prevent recurrent admissions and improve quality of life. Once admitted to the hospital, frail older adults may benefit from being congregated in a unit that specializes in their care and can provide attention to their functionality, continence, sleep disturbances, delirium, and palliative care issues.

TABLE 24-1 FOUR COMMONLY USED INSTRUMENTS TO MEASURE FRAILTY IN OLDER ADULTS, WITH RELEVANT MEASUREMENT DOMAINS AND SCORING CRITERIA

INSTRUMENT	DOMAINS	SCORING
Physical frailty (biologic syndrome model)*	Physical function (slowness, low activity, weakness), nutritive (weight loss), and exhaustion	Score range: 0-5 Frail = ≥3 criteria present Intermediate/pre-frail = 1-2 criteria present Robust = 0 criteria present
Cumulative Deficit Frailty Model (comorbidity model)†	Diseases, ability in ADL, health attitudes/values, and symptoms/signs from the clinical and neurologic examinations	Number of deficits present and divided by the number of deficits taken into consideration Higher proportion equates to a higher level of frailty
Vulnerable Elders Survey (VES-13)‡	Physical function and ADL/IADL disability	Score range: 0-10 Frail = score ≥3
1994 Frailty measure (functional domains model)§	Physical function, nutritive function, cognitive function, sensory problems	Subject scoring a 3 or higher on at least one item in any domain is considered to have a problem or difficulty in that domain Frail = problems/difficulties in ≥2 domains

ADL = activities of daily living; IADL = instrumental activities of daily living.

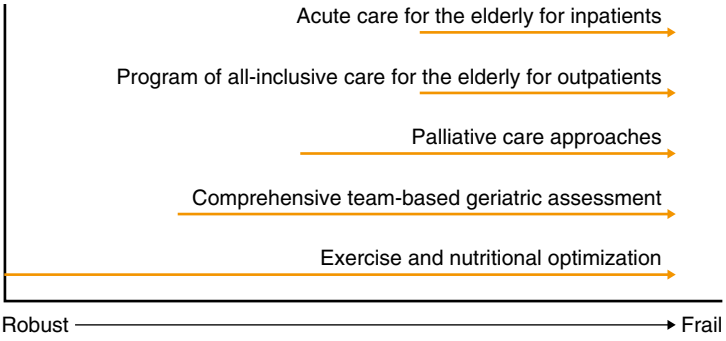

FIGURE 24-4. Assessment and treatments in frail and vulnerable older adults.

PROGNOSIS

Frailty increases the likelihood for development of influenza or influenza-like illness in the 6 months after vaccination; the likelihood of requiring care in a skilled nursing or long-term care facility after hospitalization for general surgery; the likelihood of poor outcomes in patients with cardiovascular disease; poor renal transplant graft function and early hospital readmission after transplantation; falls, hospitalization, and mortality in patients on hemodialysis for chronic renal failure; and the risk of death in aging intravenous drug users. Biologic differences between frail and non-frail older adults (see Fig. 24-1) drive the marked vulnerability to adverse outcomes observed in the frail subjects.

FALLS

Falls are a common manifestation of frailty. Contributing factors include cardiopulmonary disease, poor eyesight, hearing loss, balance disturbances, weakness, movement disorders, neuropathies, poor judgment, depression, osteoporosis, arthritis, and foot disorders.[17] The risk of falling also increases in patients who take more prescription medications, especially hypnotics, muscle relaxants, antihypertensive agents, diuretics, and antidepressant medications. Environmental risks include stairs, loose objects, rugs, poor lighting, poorly fitting shoes, uneven pavements, and slippery surfaces.

Patients who have fallen or have a fear of falling should have a falls assessment, including measuring orthostatic blood pressure, assessing vision, reviewing medications, and testing balance, gait, and lower extremity strength.[18,19] Exercise alone and exercise combined with other interventions (e.g., vision assessment and treatment; environmental modification) lower the risk compared with usual care,[A17–A19] but intensive, nurse-led, individualized plans may not provide incremental benefit over good baseline care.[A20,A21] Data on vitamin D supplementation to reduce falls have been inconclusive, but recent trials indicate no benefit.[A22,A23]

25 PRINCIPLES OF DRUG THERAPY

ROBERT B. DIASIO

Depending on the conditions, a drug may produce different effects ranging from no effect to a desirable effect to an undesirable toxic effect. Clinicians must learn how to choose the correct drug dosage for different conditions to ensure effective and safe therapy. To do so, clinicians must understand pharmacokinetics—the movement of a drug over time through the body—and pharmacodynamics—the relationship between drug concentration and drug effect (Fig. 25-1), as well as drug interactions and adverse drug responses. Genomics is increasingly helpful both for individualizing therapy as well as in the design of new drugs.[1]

PHARMACOKINETIC PRINCIPLES

Administration

The most efficient and straightforward means of administering a drug into the systemic circulation is by intravenous injection of a bolus. With this route, the full amount of a drug is delivered into the systemic circulation almost immediately. The same dose also may be administered as an intravenous infusion over a longer period, thereby resulting in a decrease in the peak plasma concentration and an accompanying increase in the time the drug is present in the circulation. Many other routes of administration can be used, including sublingual, oral, transdermal, rectal, inhalational, subcutaneous, and intramuscular; each of these routes carries not only a potential delay in the time it takes the drug to enter the circulation but also the possibility that a large fraction of it will never reach the circulation.

Absorption

Absorption refers to the transfer of a drug from the site of administration to the systemic circulation. Many drugs cross a membrane barrier by passive diffusion and enter the systemic circulation. Because passive diffusion in this setting depends on the concentration of the solute at the membrane surface, the rate of drug absorption is affected by the concentration of free drug at the absorbing surface. Factors that influence the availability of free drug thus affect drug absorption from the administration site; this effect can be exploited to design medications that release a drug slowly into the circulation by prolonging drug absorption. With certain sustained-released oral preparations, the rate of dissolution of the drug in the gastrointestinal tract determines the rate at which the drug is absorbed (e.g., timed-release antihistamines). Similarly, a prolonged drug effect can be obtained by the use of transdermal medications (e.g., nitroglycerin) or intramuscular depot preparations (e.g., benzathine penicillin G).

First-Pass Effect

Some drugs that are administered orally are absorbed relatively efficiently into the portal circulation but are metabolized by the liver before they reach the systemic circulation. Because of this "first-pass" or "presystemic" effect, the oral route may be less suitable than other routes of administration for such drugs. A good example is nitroglycerin, which is well absorbed but efficiently metabolized during the first pass through the liver. However, the same drug can achieve adequate systemic levels when it is given sublingually or transdermally.

Bioavailability

The extent of absorption of a drug into the systemic circulation may be incomplete. The bioavailability of a particular drug is the fraction (F) of the total drug dose that ultimately reaches the systemic circulation from the site of administration. This fraction is calculated by dividing the amount of the drug dose that reaches the circulation from the administration site by the amount of the drug dose that would enter the systemic circulation after direct intravenous injection into the circulation (essentially the total dose). Bioavailability can range from 0, in which no drug reaches the systemic circulation, to 1.0, in which essentially all of the drug is absorbed. The bioavailability of a drug may vary in different formulations because the overall absorption differs. This variability is a concern with the increasing use of generic preparations.

Distribution

After delivery of a drug into the systemic circulation, either directly by intravenous injection or after absorption, the drug is transported throughout the body, initially to well-perfused tissues and later to areas that are less perfused. This distribution phase can be assessed best by plotting the drug's plasma concentration on a log scale versus time on a linear scale (Fig. 25-2). For an intravenously administered drug, for which absorption is not a factor, the initial phase—from immediately after administration through the rapid fall in concentration—represents the distribution phase, during which a drug rapidly disappears from the circulation and enters the tissues. This phase is followed by the elimination phase (see later), when drug in the plasma equilibrates with drug in the tissues. During this latter phase, the drug's plasma concentration is thought to be related to drug effect.

Volume of Distribution

The volume of distribution relates the amount of drug in the body to the concentration of drug in the plasma. It is calculated by dividing the dose that ultimately gets into the systemic circulation by the plasma concentration at time zero (C_{p0}):

$$\text{volume of distribution} = \text{dose}/C_{p0} \quad (1)$$

The C_{p0} can be calculated by extrapolating the elimination phase back to time zero (see Fig. 25-2). The volume of distribution is best considered the "apparent volume of distribution" because it represents the apparent volume

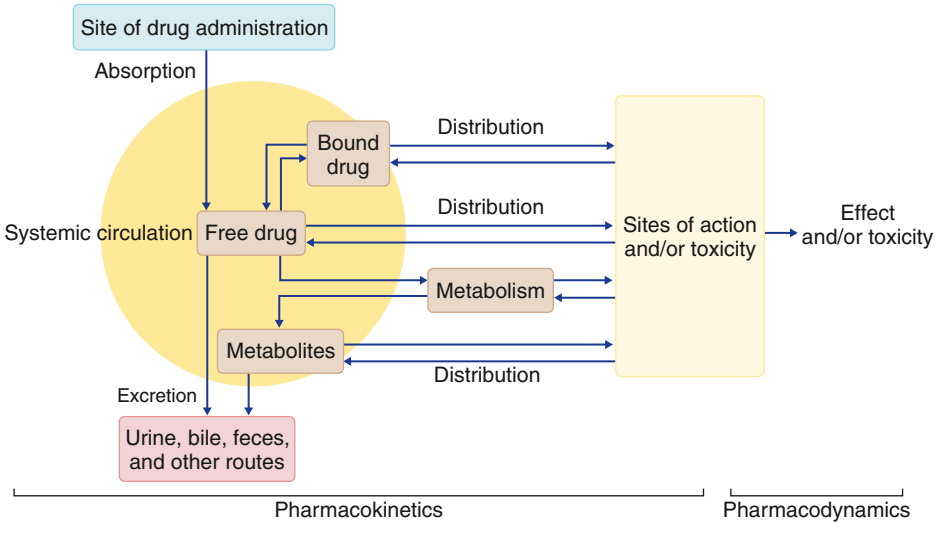

FIGURE 25-1. Schematic of a drug's movement through the body, from the site of administration to production of a drug effect. The relationship between pharmacokinetics and pharmacodynamics is shown.

ABSTRACT

The principles of pharmacokinetics help clinicians manage drug dosing and levels, including calculating a loading dose, determining a maintenance dose, and calculating how to decrease the drug level. Drug monitoring guides how to adjust dosing in various conditions, such as renal insufficiency, liver disease, and altered hemodynamic states. Knowledge of drug interactions and adverse reactions can help avoid these complications. Genomics is increasingly important, both to guide rational therapeutic decisions and for the design of new drugs.

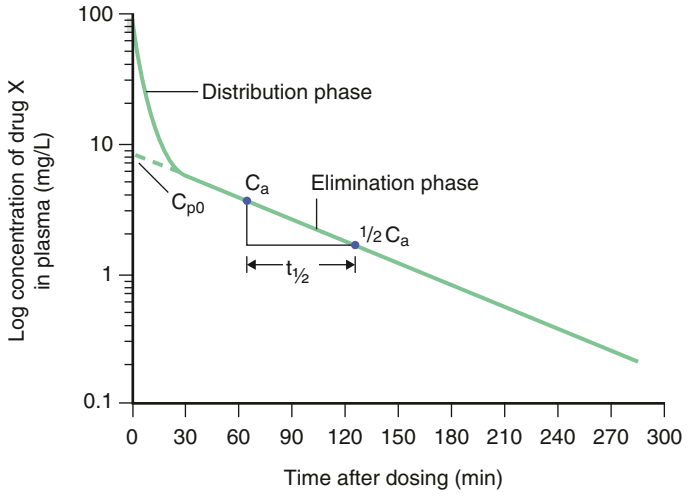

FIGURE 25-2. Representative drug concentration versus time plot used in pharmacokinetic studies. Concentration of drug is plotted with a logarithmic scale on the ordinate, and time is plotted with a linear scale on the abscissa. The resultant curve has two phases: the distribution phase, which is the initial portion of the plotted line when the concentration of drug decreases rapidly; and the later elimination phase, during which there is an exponential disappearance of drug from the plasma over time. The *dotted line* extrapolated from the elimination phase back to time zero is used to calculate plasma concentration at time zero (C_{p0}). During the elimination phase, the half-life ($t_{½}$) can be calculated as the time it takes to decrease the concentration by half (shown here as the time needed to decrease from concentration C_a to ½ C_a).

needed to contain the entire amount of the drug, assuming it is distributed throughout the body at the same concentration as in the plasma. Volume of distribution can vary widely for commonly used drugs (E-Table 25-1). Volume of distribution is useful for calculating a loading dose and appreciating how various changes can affect a drug's half-life.

Elimination

Drugs are removed from the body by two major mechanisms: hepatic elimination, in which drugs are metabolized in the liver and excreted through the biliary tract; and renal elimination, in which drugs are removed from the circulation by either glomerular filtration or tubular secretion. For most drugs, the rates of hepatic and renal elimination are proportional to its plasma concentration, a relationship that is often described as a "first-order" process. Two measurements, clearance and half-life, are used to evaluate elimination.

Clearance

The efficiency of elimination can be assessed by quantifying how fast the drug is cleared from the circulation. Drug clearance is a measure of the volume of plasma cleared of drug per unit of time. It is similar to the clinical measurement used to assess renal function—creatinine clearance, which is the volume of plasma from which creatinine is removed per minute. Total drug clearance (Cl_{tot}) is the rate of elimination by all processes (El_{tot}) divided by the plasma concentration of the drug (C_p):

$$Cl_{tot} = El_{tot}/C_p \quad (2)$$

Drugs may be cleared by several organs, but renal clearance and hepatic clearance are the two major mechanisms, so total drug clearance (Cl_{tot}) for most drugs is essentially the sum of renal clearance and hepatic clearance:

$$Cl_{tot} = Cl_{Ren} + Cl_{Hep} \quad (3)$$

Some drugs have clearances as low as <3 mL/minute, whereas aspirin is cleared at greater than 500 mL/minute. Aminoglycosides are cleared almost entirely by the kidneys, whereas aspirin, carbamazepine, and phenytoin are cleared less than 5% by the kidneys.

Drug clearance is affected by several factors, including blood flow through the organ of clearance, protein binding to the drug, and activity of the clearance processes in the organs of elimination (e.g., glomerular filtration rate and tubular secretion in the kidney, enzyme activity in the liver). Drug clearance is not affected by the volume of distribution of drug throughout the body because clearance mechanisms act only on drug in the circulation.

Half-Life

The amount of time needed to eliminate a drug from the body depends on the clearance and the volume of distribution. The first-order elimination constant (K_e) represents the proportion of the apparent volume of distribution that is cleared of drug per unit of time during the drug's exponential disappearance from the plasma over time (elimination phase):

$$K_e = \text{Cl/volume of distribution} \quad (4)$$

The value of this constant for a particular drug can be determined by plotting drug concentration versus time on a log-linear plot (see Fig. 25-2) and measuring the slope of the straight line obtained during the exponential (elimination) phase.

The time needed to eliminate the drug is best described by its half-life ($t_{1/2}$), which is the time required during the elimination phase (see Fig. 25-2) for the plasma concentration of the drug to be decreased by half. Mathematically, the half-life is equal to the natural logarithm of 2 (representing a reduction of drug concentration to half) divided by K_e. Substituting for K_e from Equation 4 and calculating the natural logarithm of 2, the half-life can be represented by the following equation:

$$t_{1/2} = 0.693 \text{ volume of distribution/Cl} \quad (5)$$

From this equation, one can predict that at any given clearance, as the volume of distribution increases, the half-life increases. Similarly, at a given volume of distribution, the half-life decreases as the clearance increases. Because a disease may affect volume of distribution and clearance differently, the half-life may increase, decrease, or not change much at all.

The half-life is useful to predict how long it takes for a drug to be eliminated from the body. For any drug that has a first-order elimination, one would expect that by the end of the first half-life, the drug would be reduced to 50%; by the end of the second half-life, to 25%; by the end of the third half-life, to 12.5%; by the end of the fourth half-life, to 6.25%; and by the end of the fifth half-life, to 3.125%. In general, a drug can be considered essentially eliminated after five half-lives, when less than 5% of the effective concentration remains.

CLINICAL APPLICATION OF PHARMACOKINETIC PRINCIPLES

Using a Loading Dose

To attain a desired therapeutic concentration rapidly, a loading dose is often used. In determining the amount of drug to be given, the clinician must consider the volume of distribution within the body into which the drug will be distributed.

$$\text{Loading dose} = \text{desired concentration} \times \text{volume of distribution} \quad (6)$$

Rapid administration of an entire loading dose may produce an initially high peak concentration that results in toxicity. This problem can be avoided either by administering the loading dose as a divided dose, by administering the drug as an infusion (with an intravenous drug), or by taking advantage of the slower access to the circulation from various other routes (e.g., oral dosing). For example, phenytoin may require a loading dose to achieve a therapeutic level (10 to 20 mg/L) rapidly. Because the volume of distribution for phenytoin is approximately 0.6 L/kg, the loading dose (see Equation 6) is 420 mg/L to attain a minimally therapeutic level of 10 to 20 mg/L in a 70-kg adult. However, administration of 420 mg of phenytoin by intravenous bolus carries the risk for cardiac arrest and death. By taking advantage of the reduced bioavailability (F = 0.8) and slow absorption of oral phenytoin, the loading dose can be administered safely as an oral dose of 500 mg.

The equation for the loading dose can also be used to calculate the dose needed to "boost" an inadequate blood level of drug to a desired therapeutic range. If therapeutic monitoring (see later under Drug Monitoring as a Guide to Therapy) shows that the phenytoin level is 5 mg/L and the desired level is 15 mg/L, it is necessary to multiply the difference needed to achieve the desired concentration (15 mg/L) by the volume of distribution (0.6 L/kg) to determine the dose (in mg/kg) necessary to achieve this drug level. In a 70-kg individual, 0.6 mg/kg is multiplied by 70 kg to obtain the calculated loading dose (420 mg) that can be administered safely. A 500-mg oral dose with a bioavailability of less than 1 (e.g., F = 0.8) would deliver to the systemic circulation the approximate amount needed and avoid the risks associated with rapid intravenous administration.

E-TABLE 25-1 PHARMACOKINETIC PARAMETERS FOR SOME COMMONLY USED DRUGS

DRUG	VD (L/kg)	PROTEIN BINDING (%)	TOTAL CLEARANCE (mL/min)	% OF TOTAL CLEARANCE AS RENAL CLEARANCE	HALF-LIFE (hr)	THERAPEUTIC RANGE (mg/L)*
Amoxicillin	0.47	17-18	417	86	1.2	2-8
Aspirin (acetylsalicylic acid)	0.14-0.18	80-90	575-725	<2	0.2-0.3	20-250
Carbamazepine	1.2	75-90	50-125	1-3	12-17	4-12
Lithium carbonate	0.7-1	0	20-40	95-99	20-270	0.1-0.4
Phenytoin	0.4-0.8	88-93	167	<5	7-42	10-20
Vancomycin	0.4-1	52-60	65	85	4-6	5-40

*Therapeutic range may vary according to the indication for the drug. For example, lithium carbonate in the range of 0.4-1.3 mg/L is appropriate for affective schizophrenia disorder, whereas a range of 1.0-1.4 mg/L is appropriate for mania. NOTE: The therapeutic range is listed to provide a sense of values often seen rather than an idealized therapeutic drug level range to be attained.
VD = volume of distribution.

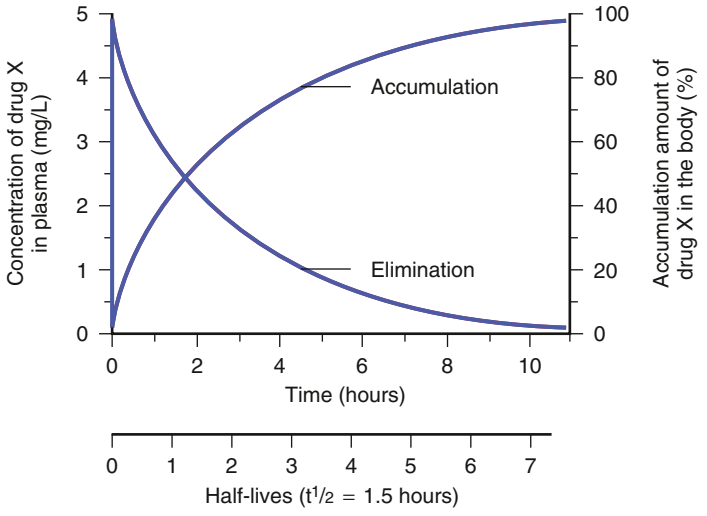

FIGURE 25-3. **Representative plot of the mirror-image relationship between the elimination of drug (after drug is discontinued) and the accumulation of drug (during infusion).** The plot shows the concentration on the left *y*-axis and time on the upper *x*-axis. The lower *x*-axis shows the time in half-lives, and the *y*-axis on the right shows the percentage of drug in the body. After five half-lives, elimination is essentially complete, and accumulation is essentially at a steady state.

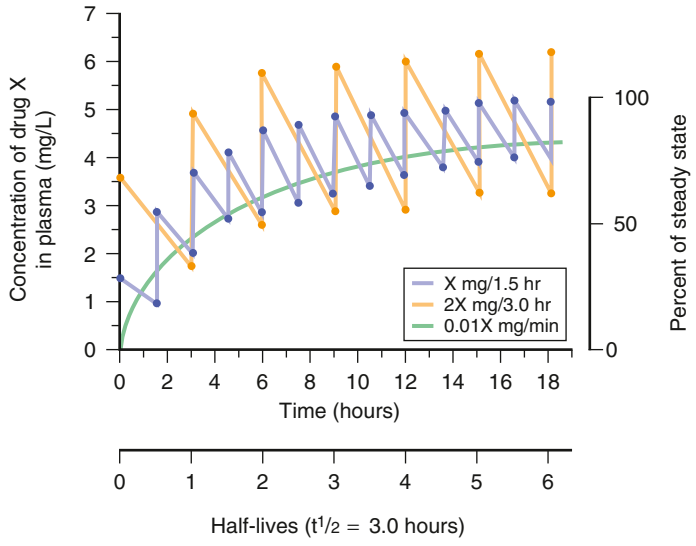

FIGURE 25-4. **Accumulation of drug over time, approaching a steady state.** Time is depicted in hours (upper *x*-axis) and half-lives (lower *x*-axis, showing that steady state is reached in approximately five half-lives). The *green line* depicts the pattern produced by an infusion of a hypothetical drug at a dose of 0.01X. The *orange line* shows the pattern resulting from oral administration of a 2X dose every 3 hours, and the *blue line* represents the pattern produced by oral administration of dose X every 1.5 hours.

Determining Drug Accumulation

Continuing to administer a drug, either as a prolonged infusion or as repeated doses, results in accumulation until the drug level reaches a steady state at which plasma and tissue levels remain constant because the amount of drug being administered equals the amount being eliminated. The elimination half-life determines not only the time course of drug elimination but also the time course of drug accumulation (Fig. 25-3). As with drug elimination, five half-lives is the approximate time needed to reach steady state during drug accumulation. Whereas drugs with short half-lives accumulate rapidly, drugs with long half-lives require a longer time to accumulate, thereby potentially delaying the achievement of therapeutic levels. For drugs with long half-lives, a loading dose may be needed to obtain rapid drug accumulation and a more rapid therapeutic effect.

With each change in drug dose or rate of infusion, a change in steady state occurs. Although it is not obvious for drugs with short half-lives, the effects of dose adjustments for drugs with longer half-lives are delayed, and the time varies directly with the drug's half-life.

Using a Maintenance Dose

After steady state is reached in approximately five half-lives, with either a continuous infusion or intermittent doses, the rate of drug administered equals the rate of drug eliminated. For an intravenous drug, the administration rate is the infusion rate (I); for a drug administered by another route (e.g., orally), the administration rate is the dose per unit of time (D/t). Equation 7 shows that the rate of elimination (total) equals $Cl_{tot} \times C_p$. With an intravenously administered drug, because the infusion rate equals the elimination rate at steady state, it follows that

$$I = Cl_{tot} \times C_p \quad (7)$$

Similarly, with an orally administered drug, the dose administered per unit of time equals the elimination rate at steady state, with the result that

$$D/t = Cl_{tot} \times C_p \quad (8)$$

These equations show the direct relationship between the dose and the resultant plasma concentration at steady state. This relationship is independent of the distribution of the drug. By use of these equations, it is possible to determine the infusion rate or the interval and dose needed to achieve and maintain a specified drug concentration in the plasma.

When a drug is administered intermittently, it approaches steady-state concentration over time, with a pattern similar to that observed with continuous infusion (Fig. 25-4). With intermittent drug administration, such as with an oral dose, the drug concentration fluctuates; the magnitude of fluctuation between the peak and trough concentrations depends on the interval of administration, drug half-life, absorption characteristics, and site of administration. As the intervals decrease below the half-life, the fluctuation decreases and approaches the curve produced by an intravenous infusion. With timed-release formulations, orally administered drugs reach peak concentration more slowly but persist longer in the plasma.

Decreasing the Drug Level

At times, it may be necessary to decrease the plasma drug level while maintaining therapy (e.g., when signs of toxicity become apparent or a potentially dangerously high concentration of drug is noted; see later). The most effective and rapid response is to discontinue the drug; the length of time for which the drug is discontinued is determined by the estimated half-life of the drug in the specific patient. After discontinuation of the drug for a time based on its half-life, the total clearance (Cl_{tot}) of the drug can be used to determine what infusion rate (I, Equation 7) or dose and interval (D/t, Equation 8) must be used to achieve the new desired concentration (C_p).

Effect of Dose Increases on Elimination Kinetics

Not all drugs behave the same when the dose is increased. For most drugs, elimination follows first-order or linear kinetics; the amount of drug eliminated is directly proportional to the concentration of drug in the plasma (Fig. 25-5A). However, a few drugs have a different pattern of elimination. For example, ethanol, phenytoin, and aspirin have dose-dependent, nonlinear saturation kinetics. As the dose of drug increases and the concentration of drug in the plasma rises, the relative amount of drug being eliminated falls (i.e., the clearance decreases) until the rate of drug metabolism is at its maximum. At this point, drug elimination is said to be zero order, and the drug concentration in plasma starts to increase much more (no longer linearly) with each subsequent increase in dose (Fig. 25-5B).

DRUG MONITORING AS A GUIDE TO THERAPY

Although published pharmacokinetic data (usually population averages) are useful to determine initial drug dosing, modification of the dose may be needed in an individual patient. For some drugs (e.g., certain antihypertensive agents or anticoagulants), the therapeutic effects (e.g., blood pressure or coagulation) can be quantified easily over a range of concentrations, thereby permitting adequate drug adjustment. For many other drugs (e.g., some antiarrhythmic or antiseizure medications), therapeutic effects over a range of concentrations are not readily detectable. With these drugs, the plasma concentration may provide further guidance in optimizing therapy if the plasma concentration of the drug is a reflection of its concentration at the site of action and the drug effects are reversible. A third, much smaller group of drugs produces irreversible effects (e.g., aspirin inhibition of platelet aggregation). With these drugs, plasma drug concentration does not correlate with drug effect, and drug monitoring is not useful.

To use drug concentration as a guide to therapy, the range of effective but safe concentrations, or the *therapeutic window*, is usually determined from a dose-response curve generated from a population of patients who have been examined closely for therapeutic and toxic effects (Fig. 25-6). The *therapeutic*

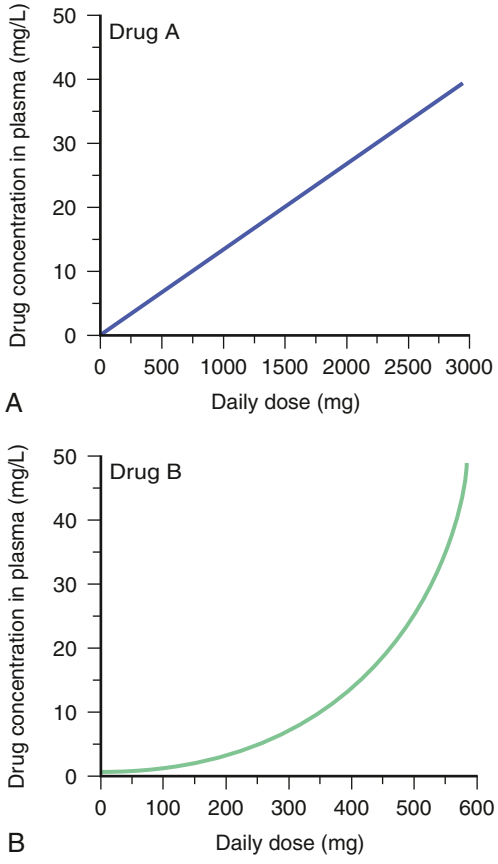

FIGURE 25-5. **Effect of increasing the dose of a drug on its serum concentration. A, Drug A follows first-order or linear kinetics. B, Drug B follows zero-order or nonlinear (or saturable) kinetics.**

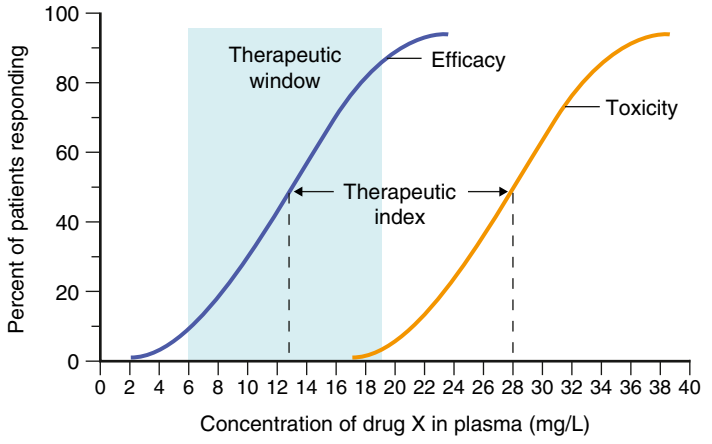

FIGURE 25-6. **Pattern produced in a dose-response population study in which both effect and toxicity are measured. The therapeutic window is shown as the range of therapeutically effective concentrations, which includes most of the efficacy curve and less than 10% of the toxicity curve. The therapeutic index is calculated by dividing the 50% value on the toxicity curve by the 50% value on the efficacy curve.**

index, which is a useful measure of drug toxicity, is calculated by dividing the 50% value from the toxicity curve by the 50% value from the efficacy curve. Because these curves are generated from population data, the values may not be applicable to all individuals.

Drug monitoring is especially useful when a drug is used to treat a serious or life-threatening disease and it is essential to avoid inadequate doses (because a therapeutic effect is often critical) as well as excessive doses (because of the risk for toxicity). In contrast, it is not necessary to assay levels of drugs used to treat noncritical diseases (when inadequate treatment is not a serious problem) or for which the therapeutic index is large (when relative overtreatment is not likely to produce toxicity).

Problems with Interpreting Drug Concentration

The time of blood collection, perhaps more than any other factor, contributes to the misinterpretation of drug levels. If sampling is performed too early, while the drug is still in the distribution phase, the drug level may be high and not reflect drug concentration at the site of action. It is therefore important to sample after the distribution phase.

For many drugs administered intermittently, such as intravenous antibiotics (e.g., vancomycin), a trough level, which is obtained immediately before the next dose is administered, is most useful for making decisions about dose adjustments. For drugs administered by infusion or intermittently at short intervals, the best time to draw blood is during steady state.

Protein binding is another major factor that contributes to the misinterpretation of drug levels. Free drug (not bound to protein and able to equilibrate with tissues and to interact with the site of action) is the critical drug concentration when therapeutic decisions are being made. Many drugs are tightly bound to plasma protein, however. Many commonly used drugs (e.g., aspirin, carbamazepine, and phenytoin), have protein binding of more than 75%, so assessment of the total drug level may not be helpful. Unfortunately, assessment of the "true" free drug concentration also may be inaccurate, particularly if the fraction of drug bound to protein varies. In addition, the drug's binding may be decreased by disease or by other drugs, thereby leading to increased unbound drug levels that alter the interpretation of the measured drug concentrations. Kidney and liver disease can change the binding of certain drugs (e.g., phenytoin) to protein because of a decrease in protein (e.g., decreased albumin, as in nephrotic syndrome or liver disease) or as a result of competition for protein binding by endogenously produced substances (e.g., uremia in kidney disease, hyperbilirubinemia in liver disease). Similarly, other drugs being administered may compete for binding to protein. A major problem secondary to these changes in protein binding is that free drug is not typically measured in many of the common drug assays used by clinical laboratories. Lastly, changes in drug binding to protein can affect the pharmacokinetics of the drug; the volume of distribution increases as protein binding decreases.

The usefulness of a drug assay is also limited by physiologic changes that may alter the response at a particular drug concentration. An example is the response produced by increasing levels of phenytoin in the presence of reduced protein binding (e.g., with hypoalbuminemia or renal impairment), where changes in phenytoin's blood concentration will be exaggerated.

Tolerance, which is a reduced response to a given concentration of drug with continued use, is commonly observed with the continued use of opioids (e.g., in terminal cancer patients). After long-term administration, the same drug concentration is no longer associated with the same pain relief. Positive (placebo) or negative (nocebo) effects may also be associated with many drugs and may mimic their known benefits or toxicities.[2]

ADJUSTMENTS OF DRUG DOSE WITH DISEASE

Kidney Disease

The major questions to be answered when determining whether a drug dosage needs to be adjusted in the setting of kidney disease are: is the drug primarily excreted through the kidneys, and are increased drug levels likely to be associated with toxicity? If the answer to both questions is yes, a drug is likely to accumulate and become toxic as renal clearance decreases unless the drug dose is reduced.

To obtain the desired concentration over time in the presence of decreased clearance, adjustments can be made by decreasing the dose while maintaining the dose interval, maintaining the dose but increasing the interval between doses, or a combination of both (E-Table 25-2). With these adjustments, it may be possible to achieve an average concentration similar to that obtained with normal renal function, but there may be concomitant marked changes in the magnitude of peak and trough values. In choosing the type of drug adjustment, the clinician should consider not only the therapeutic index of the drug but also whether an effective concentration must be achieved quickly and maintained within a narrow range (i.e., maintaining an average drug concentration and avoiding trough levels at which the drug is ineffective); and whether toxicity is associated with elevated (i.e., peak) drug concentrations.

Renal drug clearance correlates with creatinine clearance (whether the drug uses glomerular filtration or tubular secretion), so any adjustment of drug dose in kidney disease can use the creatinine clearance to estimate the dose needed. The creatinine clearance (Cl_{cr}), which is used as an estimate of glomerular filtration rate, may be calculated directly from the serum creatinine concentration by the following equation:

$$Cl_{cr} = [(140 - \text{age}) \times \text{weight (kg)}] / [72 \times \text{serumcreatinine (mg/dL)}] \quad (9)$$

E-TABLE 25-2 EXAMPLES OF ADJUSTMENTS TO DRUG DOSES IN RENAL FAILURE

		HALF-LIFE (HR)			*ADJUSTMENT FOR RENAL FAILURE*			
DRUG	**TYPE OF ELIMINATION**	**NORMAL**	**END-STAGE RENAL DISEASE**	**METHOD***	**GFR > 50 mL/min**	**GFR 10-50 mL/min**	**GFR < 10 mL/min**	**REMOVED BY DIALYSIS†**
Amikacin	Renal	2-3	30	DD II	60-90% 12 hr	30-70% 12-18 hr	20-30% 24 hr	Yes
Aspirin	Hepatic (renal)	2-19	Unchanged	II	4 hr	4-6 hr	Avoid	Yes
Carbamazepine	Hepatic (renal)	35	?	DD	Unchanged	Unchanged	75%	No
Lithium carbonate	Renal	14-28	Prolonged	DD	Unchanged	50-75%	25-50%	Yes
Phenytoin	Hepatic (renal)	24	8	DD	Unchanged	Unchanged	Unchanged	No
Tobramycin	Renal	2.5	56	DD II	60-90% 8-12 hr	30-70% 12 hr	20-30% 24 hr	Yes
Vancomycin	Renal	6-8	200-250	II	24-72 hr	72-240 hr	240 hr	No

*DD (alone) = decrease dose (maintain same interval); II (alone) = increase interval between doses (maintain dose); DD and II (together) = combination of both approaches.
†Dialysis refers to hemodialysis.
GFR = glomerular filtration rate.

The calculated creatinine clearance should be multiplied by 0.85 for females when the serum creatinine concentration is less than 5 mg/dL and renal function is not rapidly changing.

Using Clearance for Dose Adjustment

The dose of a drug used in renal insufficiency ($dose_{D\text{-}RI}$) is proportional to the dose used with normal renal function ($dose_D$) in the same ratio as clearance of the drug in renal insufficiency ($Cl_{D\text{-}RI}$) to clearance with normal renal function (Cl_D). By rearranging, $dose_{D\text{-}RI}$ is defined as:

$$Dose_{D\text{-}RI} = dose_D \times [Cl_{D\text{-}RI}/Cl_D] \quad (10)$$

The $Cl_{D\text{-}RI}$ can be estimated by multiplying Cl_D by the ratio of the creatinine clearance in renal insufficiency ($Cl_{cr\text{-}RI}$) over Cl_{cr} with normal renal function:

$$Cl_{D\text{-}RI} = Cl_D \times [Cl_{cr\text{-}RI}/Cl_{cr}] \quad (11)$$

As shown in Equation 3, total clearance is the sum of clearance by renal and nonrenal (typically hepatic) mechanisms. Any nonrenal clearance is assumed to remain normal, and only the renal clearance is adjusted, with total clearance being reduced only to the extent that renal clearance is reduced. The dose may be calculated from the total (adjusted) clearance and the desired plasma concentration by either Equation 7 or Equation 8.

However, the calculated dose is only an initial guide to the needed dose. By monitoring the drug response or the plasma drug concentration at various times after initial dosing, further dose adjustments can be made as necessary. From a practical perspective, most clinical dose adjustments in the presence of renal dysfunction can be guided by published tables based on changes in glomerular filtration rate and the effectiveness of dialysis in removing the drug. Computerized decision support systems are particularly effective in guiding medication dosing for inpatients with renal insufficiency.

Loading Dose in Renal Insufficiency

For drugs that are typically administered with a loading dose in patients with normal renal function, the same approach can be used in patients with renal insufficiency to ensure that the desired concentration is achieved rapidly. For drugs typically administered without a loading dose, the prolonged half-life that results from renal insufficiency may delay the time required to reach a steady state. In this setting, a loading dose (equal to the amount needed to reach steady state with normal renal function) should be followed by lower or less frequent maintenance doses.

Liver Disease

Although many drugs are biotransformed in the liver, no useful laboratory test can guide dose adjustments. If the liver's capacity to produce protein (reflected by a low albumin concentration and prolonged prothrombin time) is reduced significantly, the clearance of drugs metabolized by the cytochrome P-450 enzymes is probably reduced as well.

One special situation that can develop with chronic liver disease and may require dose adjustment is portal hypertension with a portacaval shunt (Chapter 139). In this situation, hepatic blood flow decreases and hepatic clearance also decreases, thereby reducing the first-pass effect and resulting in higher concentrations of drug reaching the systemic circulation. Drugs with a large hepatic extraction that are typically administered orally (e.g., propranolol to lower portal vein pressure) may appear in the systemic circulation at higher, potentially toxic concentrations.

Hemodynamic Diseases

Decreased cardiac output and hypotensive conditions lead to decreased perfusion of the organs, including those responsible for eliminating drugs. The drug dose can be adjusted for decreased renal perfusion by the use of creatinine clearance. The effect of decreased hepatic blood flow on pharmacokinetics is more difficult to assess. For drugs that have a high hepatic extraction (e.g., lidocaine), decreased hepatic blood flow suggests a need for dose reduction.

Altered hemodynamics also may affect the distribution of selected drugs. Drugs that have a relatively large volume of distribution (e.g., lidocaine) may be affected by conditions leading to hypotension, such as shock, thereby resulting in a decrease in the apparent volume of distribution and a need to reduce the loading dose to avoid potentially toxic drug levels.

In general, in the setting of severely compromised hemodynamics, it is advisable to be conservative and to avoid potentially toxic loading and maintenance doses. Drug levels and the clinical status should be monitored closely, and drug doses should be adjusted as necessary.

TABLE 25-1 GENERAL RECOMMENDATIONS FOR DRUG USE IN ELDERLY PATIENTS

- Clearance of drugs eliminated by the kidneys may be reduced by 50%.
- Drugs eliminated primarily by the liver typically do not require dose adjustments for age, except for drugs with high hepatic clearances, which may be affected by the age-related decrease in hepatic blood flow.
- Because of the potential for increased target organ sensitivity in elderly people, only the lowest effective dose should be used.
- Frequent reviews of the patient's drug history should be conducted, including both prescription and over-the-counter medications, keeping in mind the increased potential risk for drug interactions and adverse drug responses.

APPROACH TO DRUG OVERDOSE

The pharmacokinetic principles discussed earlier can be used to determine the best approach for drug removal in the setting of a drug overdose (Chapter 96), particularly if hemodialysis or hemoperfusion remove a substantial fraction of the total body load of drug. For drugs with a large volume of distribution (e.g., warfarin), only a small amount can be removed because clearance affects only the amount of drug present in the plasma, and a large portion of the drug is outside the plasma compartment. Similarly, for a drug with high clearance value (e.g., metformin), hemoperfusion may increase the overall clearance only minimally and is not indicated.

DRUG USE IN ELDERLY PATIENTS

Administering drugs to elderly patients (Chapter 24) is perhaps the most challenging area of adult therapeutics because of several factors: the increasing likelihood of multiple illnesses, often with multisystemic involvement; the need for these patients to take multiple drugs (often prescribed by different physicians); and the increasing probability of altered pharmacokinetics and pharmacodynamics. These factors together contribute to a significantly increased frequency of drug interactions and adverse drug responses in this group of patients (Table 25-1).

Pharmacokinetic Changes with Age

Pharmacokinetic changes can be secondary to the general physiologic effects of aging, such as alteration in body composition, or to specific changes in pharmacokinetically important organs (e.g., kidneys, liver). The distribution of drugs tends to change dramatically with age, mainly because of changes in body composition. Most typical is the increase in total body fat, with the accompanying decrease in lean body mass and total body water. The concentration of plasma proteins may also change; in particular, the albumin level may decrease as the liver ages. For water-soluble drugs that are not bound to plasma proteins, the apparent volume of distribution is reduced; in contrast, for lipid-soluble drugs, the volume of distribution is increased. Changes in metabolism also accompany aging, but these changes alone do not typically account for altered pharmacokinetics.

The clearance of many drugs is decreased in the elderly because cardiac output and blood flow to the kidneys and liver may be decreased. Glomerular filtration rate may be reduced by 50%. Hepatic elimination of drugs is less affected, except for drugs with a high hepatic clearance (e.g., lidocaine). The elimination half-life of many drugs is increased with aging as a consequence of a larger apparent volume of distribution and a decreased hepatic or renal clearance (see Equation 5).

Pharmacodynamic Changes with Age

Pharmacodynamic changes are a result of changes in the responsiveness of the target organ. Elderly individuals typically require lower drug doses, even if the pharmacokinetics are little changed. For example, antianxiety drugs and drugs from the sedative-hypnotic class may produce increased central nervous system depression in elderly patients at concentrations that are well tolerated in younger adults.

INTERACTIONS AMONG DRUGS

Because patients are typically treated with multiple agents, even for a single disease, the possibilities for drug interactions are great. Many clinically important drug interactions typically involve a drug with a low therapeutic index (e.g., warfarin) and an easily detectable pharmacologic effect (e.g., bleeding), such that a small increase in the amount of drug produces a significant effect (toxicity).

It is difficult to assess the prevalence of drug interactions in either the inpatient or the ambulatory setting, particularly because no formal and comprehensive

surveillance mechanism is available. However, the risk for drug interactions seems to be increasing, particularly for critically ill, hospitalized patients who are frequently taking more than 10 medications.[3]

There are basically two types of drug interaction: pharmacokinetic drug interactions, caused by a change in the amount of drug or active metabolite at the site of action; and pharmacodynamic drug interactions (without a change in pharmacokinetics), caused by a change in drug effect.

Pharmacokinetic Drug Interactions

Less Drug at the Site of Action

Decreased Absorption

The gastrointestinal lumen is perhaps the best example of an area where drug interactions can result in decreased drug absorption. Some commonly used drugs can illustrate this type of interaction. For many drugs, a physicochemical interaction prevents the drug from being absorbed. For example, metal ions (e.g., aluminum, calcium, and magnesium in antacids and iron in supplements to treat iron deficiency) form insoluble complexes with tetracyclines and can act as chelating agents. Other commonly used medications that decrease absorption include kaolin-pectin suspensions, which are used to treat diarrhea and can significantly inhibit the absorption of coadministered drugs.

Drugs that are particularly susceptible to changes in pH may have decreased absorption when they are administered with other drugs that either affect gastric acidity or alter the extent of exposure to low pH. Proton pump inhibitors or histamine-2 receptor antagonists may elevate gastric pH, which can inhibit the dissolution and subsequent absorption of drugs that are weak bases (e.g., ketoconazole). Medications that delay gastric emptying (e.g., belladonna alkaloids) can increase the degradation of a coadministered acid-labile drug (e.g., levodopa), thereby resulting in decreased absorption.

Altered Distribution

Drugs that use the same active transport process to reach their site of action can compete at the level of transport, thereby resulting in lower levels of drug reaching that site. Examples of this type of interaction include the interaction of phenothiazines (e.g., chlorpromazine) with tricyclic antidepressants (e.g., amitriptyline).

Increased Metabolism

Many drugs (e.g., phenytoin, ethanol, griseofulvin, rifampin) and toxic compounds (e.g., cigarette smoke, certain chlorinated hydrocarbons) can increase the hepatic metabolism of other drugs (e.g., corticosteroids, cyclophosphamide, cyclosporine, certain β-adrenergic blockers, theophylline, warfarin) by inducing the activity of the cytochrome P-450 super family of monooxygenase enzyme (see medicine.iupui.edu/clinpharm/ddis/ for more information).

More Drug at the Site of Action

Increased Absorption

Any drug that increases the rate of gastric emptying (e.g., metoclopramide) can potentially increase the absorption of acid-unstable drugs. Also, drugs that decrease intestinal motility (e.g., anticholinergics) may increase the absorption of drugs that are relatively poorly absorbed (e.g., metformin) by increasing the drug's contact time with the absorbing surface.

Altered Distribution

Drugs bound to protein are limited in their distribution (particularly at the site of action) and are not available for metabolism or excretion. Drugs can compete with each other for binding to plasma proteins, resulting in drug interactions. Phenytoin and warfarin are both greater than 90% bound to protein. When both are coadministered, phenytoin can displace warfarin, thereby leading to an increased anticoagulant effect and possible bleeding.

Decreased Metabolism

One of the most impressive drug interactions is produced when one drug inhibits the metabolism of another, thereby leading to the second drug's accumulation and a significant risk for toxicity. An example of this type of interaction occurs when 6-mercaptopurine, an antileukemic drug with a low therapeutic index, is used with allopurinol, often administered to control hyperuricemia. The interaction may result in potentially life-threatening toxicity.

Some drugs can inhibit the metabolism of many other drugs because many drugs share the same metabolic pathway. This consideration is particularly relevant for drugs that share CYP-450 pathways. It is estimated that CYP2D6 accounts for the metabolism of approximately 25% of all currently prescribed drugs, including antidepressants, neuroleptics, β-blockers, opioids, antiemetics, antiarrhythmics, and even some cancer chemotherapy drugs. Some commonly used drugs such as cimetidine can inhibit the metabolism of drugs from several different classes, such as diazepam, imipramine, lidocaine, propranolol, theophylline, and warfarin. Agents such as amiodarone inhibit the metabolism of calcium-channel blockers, phenytoin, and warfarin. Of particular importance with amiodarone is its half-life of 1 to 2 months; it continues to inhibit drug metabolism for several months after it has been discontinued.

Other drugs are notable because their metabolism is inhibited by a variety of different drugs. The metabolism of warfarin is inhibited not only by cimetidine and amiodarone but also by many other drugs, including alcohol, allopurinol, disulfiram, metronidazole, phenylbutazone, sulfinpyrazone, and trimethoprim-sulfamethoxazole. Similarly, the metabolism of phenytoin is inhibited by chloramphenicol, clofibrate, disulfiram, isoniazid (slow acetylators; see Table 25-3), phenylbutazone, and valproic acid.

Although most of these examples involve enzymes that metabolize the drug within the liver, drug-metabolizing enzymes outside the liver also may be affected by certain drugs. Perhaps the best-known example is monoamine oxidase, which can be affected by nonspecific monoamine oxidase inhibitors, thereby resulting in the accumulation of catecholamines at multiple sites after their release in response to the eating of tyramine-containing foods such as aged cheese, aged or cured meats, and any spoiled meat, poultry, or fish.

Decreased Excretion

Drugs can compete for the active transporters present in the kidney. Most of these interactions involve the acid transporters. The best-known interaction is probenecid's inhibition of penicillin transport, thereby leading to decreased penicillin clearance and thus higher plasma levels, an interaction that was helpful when penicillin was in short supply. A similar inhibitory effect on the renal excretion of methotrexate can be produced by salicylates, phenylbutazone, and probenecid. The active transport of basic drugs (e.g., metformin and dofetilide) can also be inhibited by other drugs (e.g., cimetidine).

Pharmacodynamic Drug Interactions

With pharmacodynamic interactions, drugs interact at the level of the receptor (target) or may produce additive effects by acting at separate sites on cells. An example of the first is the interaction of a β-blocker with epinephrine, which blocks β-adrenergic receptors; as a result, the α-adrenergic effects of epinephrine are unopposed. This undesirable interaction can result in severe hypertension. The additive effects of drugs are exemplified by aspirin, which can increase the bleeding time by acting on platelets, and direct-acting oral anticoagulants, which affect clotting (Chapter 70). The result is an increased risk for hemorrhage. Similarly, β-adrenergic blockers and calcium-channel blockers have additive negative inotropic effects when they are coadministered.

DIAGNOSIS AND PREVENTION OF DRUG INTERACTIONS

For a drug interaction to be recognized, the index of suspicion must be high, particularly whenever multiple drugs are used together. Several clinical settings should raise concern about the possibility of drug interactions and alert the clinician as to how to avoid them (Table 25-2). Because of the ever-increasing list of known and suspected drug interactions, it is impossible for a clinician to remember all or even many of the possible interactions, so it is best to consult one of a number of websites (e.g., www.drugs.com/drug_interactions.html and reference.medscape.com/drug-interactionchecker) that maintain current information on drug interactions.

Another type of drug interaction is between components of food (e.g., grapefruit juice) or natural products (e.g., herbs) and drugs. By inhibiting the intestinal CYP-450 3A4 enzyme system, grapefruit juice can raise levels of drugs metabolized by this pathway (e.g., saquinavir, cyclosporine, verapamil) and result in toxicity or adverse drug effects. It is now recognized that a number of foods and herbs can affect drug-metabolizing enzymes, such as the CYP-450s (see medicine.iupui.edu/clinpharm/ddis/).

ADVERSE REACTIONS TO DRUGS

An adverse drug response is an undesired effect produced by a drug at standard doses, which typically necessitates reducing or stopping the suspected agent and may require treatment of the noxious effect produced. Further harm may occur with continued or future therapy with the drug.

EPIDEMIOLOGY

The financial impact of adverse drug responses is estimated to be more than $100 billion per year. The actual incidence of adverse drug responses is difficult to quantify because many cases are either not recognized or not

TABLE 25-2 HIGH-RISK SITUATIONS THAT RAISE CONCERNS ABOUT POSSIBLE DRUG INTERACTIONS AND HOW TO PREVENT THEM

HIGH-RISK SITUATIONS

- The use of any drug with a low therapeutic index (e.g., anticoagulant agents, antiarrhythmic agents, anticonvulsant agents, lithium carbonate, oral hypoglycemic agents).
- As the number of drugs being used concurrently increases, the risk for drug interactions disproportionately increases, particularly with more than 10 drugs.
- Critically ill patients who have multisystemic disease with compromised renal, hepatic, cardiac, or pulmonary function.
- Patients who have the acquired immunodeficiency syndrome or an immunocompromised state.
- Patients with various behavioral and psychiatric disorders (e.g., patients who take many prescription drugs as well as illicit drugs and alcohol).

STEPS CAN BE TAKEN TO PREVENT DRUG INTERACTIONS

- When taking the medical history, document all drugs the patient is taking (and has recently taken), including prescription, over-the-counter, and other addictive drugs.
- Minimize the number of drugs being taken by frequently reviewing the patient's drug list to ensure that each drug continues to be needed.
- Have a high degree of suspicion when medications that have a low therapeutic index and are known to have a high risk for drug interactions are used.
- Be especially alert in high-risk clinical settings, such as occur with critically ill patients.
- Consider adverse drug interactions in the differential diagnosis whenever any change occurs in a patient's course.

reported. The incidence may approach 20% for outpatients (even higher for patients taking more than 15 drugs) and 2 to 7% for inpatients. The incidence of adverse drug responses increases exponentially with more than four drugs. Meta-analyses of several prospective studies suggest that adverse drug responses are now the fourth leading cause of death in hospitalized patients. Each year, adverse drug events cause an estimated four emergency department visits per 1000 individuals in the United States, with an estimated 100,000 drug-related emergency hospitalizations just in patients older than age 65 years. The most common drug classes implicated are anticoagulants, antibiotics, diabetes drugs, and opioid analgesics.[4] The incidence of adverse drug responses is likely to increase because of more prescribed and over-the-counter medications being used. Electronic medical records have the potential to predict adverse drug events and hopefully to prevent them.[5,6]

PATHOBIOLOGY

Most adverse drug responses are caused by an exaggerated (but predictable) pharmacologic effect of the drug or by a toxic or immunologic effect of the drug or a metabolite (not typically expected).

Predictable Toxic Responses to Drugs

Exaggerated drug responses that cause adverse drug effects may be due to any condition, including genetic factors,[7] that alter pharmacokinetics or pharmacodynamics. Molecular changes in the genes coding for drug-metabolizing enzymes include autosomal recessive polymorphisms associated with the debrisoquine-sparteine, *N*-acetylation, and mephenytoin types or classes of drugs (Table 25-3). Individuals with autosomal recessive genes are typically "poor metabolizers," with potentially altered pharmacokinetics that result in elevated plasma drug concentrations and can lead to toxicity. For example, the variability of response to warfarin (Chapter 70) is now understood to be due to single-nucleotide polymorphisms in the cytochrome P-450 2C9 *(CYP2C9)* and vitamin K epoxide reductase *(VKOR)* genes.

A particularly impressive example occurs with certain cancer chemotherapeutic agents that have a relatively narrow therapeutic window and the potential to produce severe cytotoxicity (e.g., deficiency in dihydropyrimidine dehydrogenase activity can result in life-threatening toxicity after the administration of 5-fluorouracil). These defects typically are not recognized until the patient is given the drug. They are often described as "pharmacogenetic" syndromes.

Other genetic alterations do not affect metabolism specifically and do not produce a range of quantitative changes. These defects can produce "qualitative" defects and are often associated with structural defects. The classic example is glucose-6-phosphate dehydrogenase. Individuals who are deficient in this enzyme cannot tolerate the oxidative stress produced by some drugs, thereby leading to hemolysis (Chapter 147). Drugs that can produce this clinical picture include aspirin, nitrofurantoin, primaquine, probenecid, quinine, sulfonamides, sulfones, and vitamin K. Another similar defect is deficiency of methemoglobin reductase, which results in an inability to maintain iron in hemoglobin in the ferrous state, causing methemoglobinemia (Chapter 144) after exposure to oxidizing drugs such as nitrites, sulfonamides, and sulfones.

Unpredictable Toxic Responses to Drugs

Other toxic or immunologic adverse drug responses are not predictable and are not obviously due to an increase in drug concentration (pharmacokinetic) or drug effect (pharmacodynamic). Unpredictable toxic responses include direct reactions between a drug and a specific organ (e.g., platinum-containing drugs, such as cisplatin, can produce direct toxicity in the kidney and the eighth cranial nerve, and a wide range of drugs can cause liver injury [Chapter 136]). With other drugs, metabolism to an active intermediate must occur first. With a standard dose of acetaminophen, no untoward effects occur because the relatively small amount of reactive metabolite formed by oxidative metabolism is detoxified rapidly by reduced glutathione. In the presence of an overdose (Chapter 96), the glutathione is depleted, and the remaining reactive metabolite can damage the liver.

Immunologic reactions to drugs are generally not produced by the drug alone. Similar to other low-molecular-weight compounds (<1000 D), they are typically not antigenic themselves. When a drug or reactive metabolite combines with a protein to form a drug-protein complex, it can become antigenic, capable of eliciting an immune response.

Perhaps the most impressive form of drug allergy (Chapter 234) is anaphylaxis (Chapter 233), which is due to an immunoglobulin E–mediated hypersensitivity. Many drugs from different classes have been shown to produce this type of drug allergy. The best-known example is the anaphylactic response produced by penicillin, which can occur after its administration by any route. Skin testing with penicillin G, penicilloic acid, or penicilloyl polylysine can identify patients at risk and should be performed in those with a suspected penicillin allergy who need treatment with penicillin. If the skin test result is

TABLE 25-3 GENETIC POLYMORPHISMS OF DRUG-METABOLIZING ENZYMES

TYPE	PRIMARY DRUG EXAMPLES	OTHER DRUGS THAT ARE SUBSTRATES	INCIDENCE OF "POOR METABOLIZERS" (%)	ENZYME INVOLVED
Debrisoquine-sparteine polymorphism	Amitriptyline, codeine, tamoxifen	Antidepressants, antiarrhythmics, β-adrenergic receptor–blocking drugs, codeine, dextromethorphan, neuroleptics	5-10 (Whites)	Cytochrome P-450 IID6 (CYP2D6)
Mephenytoin polymorphism	Mephenytoin	Mephobarbital, hexobarbital, diazepam, omeprazole	4 (Japanese, Chinese, 15-20)	Cytochrome P-450 IIC (CYP2C)
N-acetylation polymorphism	Isoniazid, sulfadiazine	Hydralazine, phenelzine, procainamide, dapsone, sulfamethazine, sulfapyridine, aminoglutethimide, aminosalicylic acid, sulfasalazine	40-70 (Japanese, 10-20)	*N*-acetyltransferase (NAT2)
Methyl conjugation polymorphism	Catecholamines	L-Dopa, methyldopa	25-30 (Whites)	Catechol-*O* methyltransferase (COMT)

positive, the patient must undergo desensitization before receiving penicillin. If the skin test result is negative, penicillin can be administered with caution.

DIAGNOSIS AND PREVENTION OF ADVERSE DRUG RESPONSES

Although many of the well-known adverse drug effects are due to a relatively small group of drugs, every drug has the potential to cause an adverse reaction. A physician should always consider the possibility of an adverse drug reaction in the differential diagnosis even if none has been previously reported to an updated website (e.g., www.fdable.com) for the particular drug. Health care professionals are encouraged to report any adverse events or product problems on a one-page form that can be sent by mail, fax, or electronically to the U.S. Food and Drug Administration (https://www.fda.gov/safety/medical-product-safety-information/medwatch-forms-fda-safety-reporting).

In many instances, it is readily apparent that a specific drug has produced an adverse reaction, such as the appearance of a rash in an otherwise healthy patient who was recently prescribed a single drug (e.g., penicillin).[8] In other cases, the effect produced by the drug may be difficult to discern from other disease states. In still other cases, the adverse effect may mimic the illness being treated (e.g., development of an arrhythmia in a patient being treated with an antiarrhythmic drug).

A patient's list of prescription drugs should be reviewed at each visit, and potential interactions with any nonprescription drugs should also be assessed. Screening tools[9] that can identify potentially inappropriate or unnecessary drug prescriptions can also reduce the risks of adverse drug reactions.[A1,A2]

The recent severe acute respiratory syndrome coronavirus 2 pandemic (Chapters 335 to 337) has resulted in external pressures to bring new drugs to market quickly. However, this public health crisis has also emphasized the need for the careful application of basic principles of clinical pharmacology in drug development.[10]

USEFULNESS OF GENOMIC DATA

In addition to being useful for avoiding adverse drug effects (see earlier), genomic data (e.g., the presence of a specific genetic variant) can also help inform the clinician of the optimal drug or dose for a specific patient. With oncologic drugs, genomic data from the tumor of an individual patient often can be useful in making a specific therapeutic decision (see www.fda.gov/drugs/science-and-research-drugs/table-pharmacogenomic-biomarkers-drug-labeling) (Chapter 164). An example is vemurafenib, which is an orally bioavailable, adenosine triphosphate (ATP)-competitive, small-molecule inhibitor of BRAF(V600E) kinase and which is effective against melanoma and potentially other malignancies[A3] that have a specific mutation in their *BRAF* gene—a valine-to-glutamic acid mutation at residue 600 (V600E) that results in the oncogene protein product, BRAF(V600E) kinase and markedly elevates activity in the MAPK signaling pathway.

Knowledge about tumor genetics also can guide new drug development. For example, the observation that the overall survival of patients with advanced non-small-cell lung cancer or colorectal cancer is approximately 1 to 2 years in patients who have a p.G12C mutation in their *KRAS* gene led to a search for a *KRAS*-targeted drug. Sotorasib, which is a covalent small-molecule inhibitor that irreversibly targets the cysteine residue at codon 12 of *KRAS*, thereby locking the protein into an inactive state, has shown potential activity in the treatment of several cancers that carry this mutation.[11] In contrast, genotype-guided selection of an oral P2Y12 inhibitor compared with conventional clopidogrel therapy without point-of-care genotyping did not reduce a composite end point of cardiovascular death, myocardial infarction, stroke, stent thrombosis, or severe recurrent ischemia.[A4,12]

26 PAIN

STEVEN P. COHEN

DEFINITION

In 2020, the International Association for the Study of Pain redefined pain as "an unpleasant sensory and emotional experience associated with, or resembling that associated with, actual or potential tissue damage."[1] This definition removes the connection between the perception of pain and its stimulus, and it also acknowledges that pain may occur in the absence of ongoing tissue damage, such as with fibromyalgia or phantom limb pain.[2] One implication of this construct is that pain is always subjective. Hence, a patient's report of pain should be accepted at face value in the absence of evidence to the contrary, even though some treatments may be tailored to objective evidence.

EPIDEMIOLOGY

Pain is ubiquitous in life, usually serving as a warning sign of impending or actual injury to the organism. It is older than mankind has existed, dating back to our most primitive ancestors. Pain is also a vital diagnostic clue for physicians. Pain is the most common symptom for which patients seek medical attention, with three of the top 10 reasons being osteoarthritis (Chapter 241), back pain (Chapter 369), and headaches (Chapter 367).

Recent data in the United States estimate a pain point prevalence of 20%, including 8% of people reporting high-impact chronic pain.[3] In the United Kingdom, the prevalence of chronic pain has been estimated to be 40 to 45%, with moderate-to-severe disabling pain affecting between 10.4% and 14.3% of people.

Populations at high risk for chronic pain include the elderly, people residing in rural areas, minority individuals, service members and veterans, and individuals with physical and psychological morbidities. Reasons for these disparities may include cultural issues, access to care, and differential treatment. Many chronic pain conditions including headaches, abdominal pain, and widespread pain disorders are more common in females.

PATHOBIOLOGY

The biopsychosocial model posits that biological, psychological, and social factors play a role in chronic pain (Fig. 26-1). The relationship between psychopathology in pain is bidirectional, with many conditions strongly associated with the persistence of pain after acute injury. Social factors that can negatively affect treatment include low job satisfaction, smoking, sedentary lifestyle, and secondary gain. Functional imaging has demonstrated that the brains of chronic pain patients are different than normal individuals, and that they undergo morphologic alterations such as general and disease-specific diminutions in gray matter as a consequence of chronic pain.

Nociception is the physiologic activation of specialized peripheral receptors *(nociceptors)* by stimuli that are potentially damaging to tissue (e.g., mechanical [tumor growth, incision], thermal, or chemical [ischemia or infection]). In addition to nociceptors that respond to specific stimuli, polymodal nociceptors respond to multiple modalities.

In contrast, pain is a conscious experience that results not only from activation of nociceptive pathways (sensory-discriminative component) but is also influenced by alterations in somatosensory processing following tissue injury, psychosocial factors (affective-motivational component), past experience, and expectations (cognitive-evaluative component). Once a stimulus is detected, it is converted into an electrical nerve signal through activation of transduction channels (e.g., transient receptor potential channels) expressed on the axonal membrane *(transduction)*. These action potentials are conveyed along the axons of unmyelinated (C) or thinly myelinated (A-delta) nerve fibers through specific pathways *(transmission)*. Modulation refers to the attenuation

26 PAIN

STEVEN P. COHEN

DEFINITION

In 2020, the International Association for the Study of Pain redefined pain as "an unpleasant sensory and emotional experience associated with, or resembling that associated with, actual or potential tissue damage."[1] This definition removes the connection between the perception of pain and its stimulus, and it also acknowledges that pain may occur in the absence of ongoing tissue damage, such as with fibromyalgia or phantom limb pain.[2] One implication of this construct is that pain is always subjective. Hence, a patient's report of pain should be accepted at face value in the absence of evidence to the contrary, even though some treatments may be tailored to objective evidence.

EPIDEMIOLOGY

Pain is ubiquitous in life, usually serving as a warning sign of impending or actual injury to the organism. It is older than mankind has existed, dating back to our most primitive ancestors. Pain is also a vital diagnostic clue for physicians. Pain is the most common symptom for which patients seek medical attention, with three of the top 10 reasons being osteoarthritis (Chapter 241), back pain (Chapter 369), and headaches (Chapter 367).

Recent data in the United States estimate a pain point prevalence of 20%, including 8% of people reporting high-impact chronic pain.[3] In the United Kingdom, the prevalence of chronic pain has been estimated to be 40 to 45%, with moderate-to-severe disabling pain affecting between 10.4% and 14.3% of people.

Populations at high risk for chronic pain include the elderly, people residing in rural areas, minority individuals, service members and veterans, and individuals with physical and psychological morbidities. Reasons for these disparities may include cultural issues, access to care, and differential treatment. Many chronic pain conditions including headaches, abdominal pain, and widespread pain disorders are more common in females.

PATHOBIOLOGY

The biopsychosocial model posits that biological, psychological, and social factors play a role in chronic pain (Fig. 26-1). The relationship between psychopathology in pain is bidirectional, with many conditions strongly associated with the persistence of pain after acute injury. Social factors that can negatively affect treatment include low job satisfaction, smoking, sedentary lifestyle, and secondary gain. Functional imaging has demonstrated that the brains of chronic pain patients are different than normal individuals, and that they undergo morphologic alterations such as general and disease-specific diminutions in gray matter as a consequence of chronic pain.

Nociception is the physiologic activation of specialized peripheral receptors *(nociceptors)* by stimuli that are potentially damaging to tissue (e.g., mechanical [tumor growth, incision], thermal, or chemical [ischemia or infection]). In addition to nociceptors that respond to specific stimuli, polymodal nociceptors respond to multiple modalities.

In contrast, pain is a conscious experience that results not only from activation of nociceptive pathways (sensory-discriminative component) but is also influenced by alterations in somatosensory processing following tissue injury, psychosocial factors (affective-motivational component), past experience, and expectations (cognitive-evaluative component). Once a stimulus is detected, it is converted into an electrical nerve signal through activation of transduction channels (e.g., transient receptor potential channels) expressed on the axonal membrane *(transduction)*. These action potentials are conveyed along the axons of unmyelinated (C) or thinly myelinated (A-delta) nerve fibers through specific pathways *(transmission)*. Modulation refers to the attenuation

ABSTRACT

Pain is the most common reason people seek medical attention and the leading cause of disability. Pain can be classified in a variety of ways, including acuity (chronic pain is pain persisting >3 months) and cause. Nociceptive pain results from actual or potential tissue injury, neuropathic pain results from an injury or disease that affects the somatosensory system, and nociplastic pain arises from altered nociception despite no clear evidence of tissue damage or abnormalities that affect the somatosensory system. Acuity is a strong predictor of outcome, whereas the cause of pain informs treatment decisions at all levels of care. Pain differs from the physical process of nociception in that it represents the denouement of a complex perceptual experience affected by myriad factors that include not only nociceptor activation, but also emotions, cognition, social and cultural context, and expectations.

Currently, no biomarkers or diagnostic tests can reliably identify or measure pain, so a patient's subjective pain complaints must be taken seriously, even though objective findings can and should influence treatment decisions. The goals of treatment should ideally include elucidating the cause of pain, mitigating nociception, improving quality of life, and alleviating suffering. The treatment of pain can be divided into four classes: conservative, which includes physical and psychotherapy; pharmacotherapy, which includes opioids and nonopioid analgesics; procedural interventions, which include injections and surgery; and increasingly popular integrative treatments, which include acupuncture, yoga, and chiropractic. Despite a paucity of studies evaluating an integrative approach, a widespread consensus supports that an interdisciplinary model is beneficial.

(or amplification) of pain signals through intrinsic inhibitory activity within the peripheral and central nervous systems (e.g., intrinsic brain and spinal neurons that release a plethora of neurotransmitters) before being perceived as unpleasant *(perception),* though in some cases pain signals may be enhanced during this process (e.g., wind-up). Pathologic pain results when injury- or disease-induced changes in the peripheral and/or central nervous systems lead to enhanced pain signaling. One example is *peripheral sensitization,* which is characterized by spontaneous ectopic activity in injured nerves and dorsal root ganglion cells, as well as enhanced sensitivity to stimuli.

Prolonged and repeated activation of nociceptive afferent fibers produces *central sensitization,* a state of hyperexcitability of central pain-signaling neurons with activation of *N*-methyl-D-aspartate (NMDA) receptors by glutamate. Loss of inhibitory interneurons and altered balance between descending inhibitory and excitatory modulatory mechanisms play a key role in the maintenance of pain. Other central neuroplastic changes that contribute to neuropathic pain include deafferentation hyperactivity following spinal cord or avulsion injuries, loss of large fiber inhibition, and reorganization of central connections of primary afferent fibers. Central and peripheral sensitization are considered to be the prime culprits responsible for pain induced by innocuous stimuli (allodynia) and increased pain to normally noxious stimuli (hyperalgesia), both of which are commonly observed in neuropathic pain. In some patients, this nociplastic process serves as the primary mechanism (e.g., fibromyalgia).

Nature versus Nurture

Chronic pain is a prototypical example of the interplay between genes and environment. Heritability is estimated to account for between 30% and 60% of the variance in pain response and plays a role in both the perception of acute pain and the transition to chronic pain.

A pain syndrome can result from a single gene mutation with high penetrance (e.g., primary erythromelalgia; Chapter 66), but multiple gene abnormalities usually promote a predisposition to pain, which requires a subsequent inciting event. For example, back pain, despite the large influence of environmental and psychosocial factors, is estimated to have a heritability of between 21% and 67%. Chronic pain in parents and a parent's pain-related cognitions are associated with pain in early adolescence, before degenerative processes typically manifest, and may have a genetic as well as environmental explanation.

Neuropathic, Nociceptive, Nociplastic, and Mixed Pain

Pain can be etiologically classified as nociceptive, neuropathic, nociplastic, or mixed (Tables 26-1 and 26-2). This distinction is important because it affects decision making at all levels of care (e.g., whether to obtain magnetic resonance imaging [MRI] for subacute spinal pain, what type of medications to prescribe, and prognosis).

Nociceptive pain, which is the most common type of pain, results from an injury or disease affecting somatic structures and includes conditions such as arthritis and mechanical spine pain.[4] Nociceptive pain can be subdivided into somatic pain involving injury to skin, muscles, and joints, and visceral pain, which results from pathology affecting internal organs (e.g., pancreatitis, angina, renal stones). In contrast to somatic pain, visceral pain is usually poorly localized, referred to somatic regions (e.g., myocardial ischemia radiating into the arm), and tends to be associated with a greater affective-motivational component than somatic pain. Reasons for these differences include a lower density and different types of nociceptors, and convergence with afferent pathways in the spinal cord.

Neuropathic pain,[5] which accounts for between 15% and 25% of chronic pain, is caused by a lesion or disease that affects the somatosensory system. Neuropathic pain may be associated with a greater decrement in quality of life than comparable degrees of nociceptive pain. One subtype of neuropathic pain is central pain, which manifests as a constellation of sensory, motor, and sometimes autonomic symptoms following a lesion or disease affecting the central nervous system.

Nociplastic pain[6] arises from altered nociception despite no clear evidence of actual or threatened tissue damage, no biomarkers, and no evidence of a disease or lesions affecting the somatosensory system. Formerly known as

TABLE 26-1 CLASSIFICATION AND PREVALENCE OF COMMON PAIN CONDITIONS

NEUROPATHIC		*NOCICEPTIVE*		*NOCIPLASTIC*[1]	*MIXED*
PERIPHERAL[2]	**CENTRAL**	**SOMATIC**	**VISCERAL**		
Peripheral neuropathy (1-3%) Postherpetic neuralgia (annual incidence 0.1-0.2%), lower with varicella zoster vaccine Chronic postsurgical pain (2-10% after surgery) Phantom limb pain (30-60%) Trigeminal neuralgia (0.01%) Radiculopathy/spinal stenosis (3-10%) Nerve entrapment syndromes (e.g., carpal tunnel, thoracic outlet, meralgia paresthetica; 5-10% collectively)	Central post-stroke pain (8%) Spinal cord injury (30-50%) Multiple sclerosis (25%) Parkinson disease (10%) Seizure disorder (1-3%)	Arthritis (25-40% in people >40 yr) Myofascial pain (5%-10%) Connective tissue disorders (0.2-0.5%) Burn pain[3] (annual incidence of burns requiring hospitalization 0.01%)	Endometriosis (10% in women of reproductive age) Interstitial cystitis[1,4] (0.2-1% of women) Ulcers/gastritis/esophagitis (3-9%) Cholecystitis/appendicitis (10-20% of people have gallstones and up to one third develop cholecystitis)	Irritable bowel syndrome[1] (5-15%) Fibromyalgia[1] (3-6%), generalized diffuse pain 7-13% Complex regional pain syndrome type I[1] (0.006-0.05%, 3-20% after orthopedic surgery) Temporomandibular disorder (5-12%)[1]	Headache[1] (15% for migraine, 20-30% for tension-type) Cancer[5] (lifetime prevalence 30-40%) Low back pain[6] (annual prevalence rate 15-45%) Neck pain[6] (annual prevalence rate 15-40%) Ischemic pain[7] (5-10% prevalence for peripheral vascular disease)

[1]Strong female predominance.
[2]Prevalence rates represent the proportion of the population who suffers from the condition except for phantom limb pain in which the prevalence is based on those with limb amputation.
[3]Third-degree burns may be associated with neuropathic pain.
[4]Also sometimes considered nociplastic pain (bladder pain syndrome).
[5]Neuropathic pain occurs in 20-50% of cases and may occur secondary to tumor invasion, surgery, chemotherapy, and radiation treatment.
[6]Neuropathic pain may predominate or accompany nociceptive pain in 20-50% of cases.
[7]Typically nociceptive, but long-standing pain may result in ischemic neuropathy.

TABLE 26-2 CATEGORIZATION OF PAIN STATES

CLINICAL CHARACTERISTIC	NEUROPATHIC PAIN	NOCICEPTIVE PAIN	NOCIPLASTIC PAIN
Etiology	Disease or injury affecting the nervous system	Tissue or potential tissue damage	Maladaptive changes that affect nociceptive processing
Descriptors	Lancinating, shooting, electrical-like	Throbbing, aching, pressure-like	Similar to neuropathic pain; visceral pain (irritable bowel syndrome, bladder pain syndrome) may be diffuse, aching, gnawing, or sharp
Sensory deficits	Frequent (e.g., numbness, tingling, pricking)	Infrequent and in nondermatomal or non-nerve distribution	Common, in nondermatomal or non-nerve distribution
Motor deficits	Neurologic weakness may be present	May have pain-induced weakness	Generalized fatigue common; weakness due to deconditioning
Hypersensitivity	Pain frequently evoked with nonpainful (allodynia) stimuli	Uncommon except for hypersensitivity in the immediate area of an acute injury	Very common and diffuse
Pain pattern	Distal radiation common	Distal radiation less common; proximal nondermatomal radiation frequent around anatomic structure	Diffuse spread not following anatomic referral pattern; patients often have multiple nociplastic conditions
Paroxysms	Exacerbations common and unpredictable	Exacerbations less common and associated with activity	Common, often related to psychosocial stressors
Autonomic signs	Can occur in ⅓ to ½ of patients	Uncommon	Sympathetic nervous system hyperactivity common

"functional pain syndromes," these conditions include fibromyalgia (Chapter 253), irritable bowel syndrome (Chapter 123), and some forms of chronic headache. Coexisting conditions may include augmented sensory processing (e.g., photophobia), diminished inhibitory pathways, and a higher co-prevalence of mood and sleep disorders. For example, over 50% of patients with chronic pain exhibit some form of sleep disturbance (Chapter 374), with the prevalence being even higher in nociplastic pain states.

Mixed pain disorders[7] contain components of neuropathic, nociceptive, and sometimes nociplastic pain (e.g., nonspecific low back pain). An example is cancer-related pain, which can result from tissue invasion or as a consequence of therapy (e.g., surgery, chemotherapy, and radiation therapy), can involve sensory nerves, and can be exacerbated by anxiety and sleep disorders. In some studies, mixed pain conditions account for more than 50% of chronic pain.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Multiple classification systems describe pain based on duration, anatomic source, and mechanisms. Acute pain results from injury or inflammation, has survival value, and plays a role in healing by preventing reinjury. In contrast, chronic pain is perhaps best construed as a "disease" that serves no useful purpose. Although no clear threshold defines when acute pain becomes pathologic, it is generally accepted that pain persisting beyond the expected healing period, or lasting over 3 months, constitutes chronic pain.

History

The evaluation of pain begins with a thorough history. Since no test or biomarker can reliably identify pain, a patient's pain complaints should always be taken seriously in the absence of objective evidence to the contrary.

A comprehensive history should include the location of pain, its quality, inciting event(s), exacerbating and relieving factors, associated symptoms and signs (e.g., numbness), magnitude, interference with activities, and response to prior treatments. The severity of pain should be assessed, usually on a 0 to 10 visual analogue scale, as mild (1-3), moderate (4-7), or severe (>7 on a 0-10 scale). Because there are subtle differences among pain scales, repeat assessments or response to therapy are ideally gauged using the same instrument. For mentally incapacitated patients, age-appropriate substitute scales or facial expressions can be used. In assessing response to therapy, a 30% or greater reduction in pain constitutes meaningful improvement. However, pain also must be considered in the context of functional capacity, psychologic and emotional well-being, sleep status, and ability to work.

Neuropathic pain is characterized by positive and negative symptoms. Positive symptoms reflect abnormal excitability of the nervous system, whereas negative symptoms, such as a loss of sensation, are usually the result of loss of axons/neurons. Paresthesias and other symptoms suggestive of sensory dysfunction are indicative of neuropathic pain, especially when they occur in a dermatomal or nerve distribution. Descriptors such as "shooting" and "electrical" are more apt to be associated with neuropathic pain. Other positive symptoms observed in neuropathic pain states include pain evoked by normally innocuous stimuli (allodynia) and an exaggerated or prolonged pain response to noxious stimuli (hyperalgesia/hyperpathia).

Nociceptive pain is classically exacerbated by movements that stress the anatomic structure (e.g., walking for arthritis, head movements for neck pain). "Throbbing" and "aching" tend to be identified with nociceptive pain states such as arthritis.

Nociplastic pain is typically characterized by diffuse symptoms (e.g., widespread pain, coexisting nociplastic conditions, or multiple pain locations). It is often accompanied by concomitant symptoms such as fatigue, insomnia, multiple chemical sensitivities, mild cognitive impairment (e.g., memory difficulties), and sensitivity to light and/or sound. *Mixed pain syndromes* in conditions such as cancer are characterized by more than one type of pain.

The evaluation of a patient in pain also must include a psychosocial history. Between half and two thirds of patients with chronic pain have depression (Chapter 362), anxiety disorders, somatoform disorders, or substance abuse disorders (Chapters 364 and 365).

Physical Examination

Since pain is a frequent manifestation of systemic disease, examination of the patient in pain should encompass all bodily systems. Although a finding on examination is almost never pathognomonic, it frequently helps guide diagnostic testing or treatment. Unlike acute pain, chronic pain is usually not associated with autonomic activation and altered vital signs. Numbness in the distribution of a nerve or nerve root suggests neuropathic pain, but nondermatomal sensory changes can accompany nociplastic and nociceptive pain as well. Focal allodynia and hyperalgesia are hallmarks of neuropathic pain. The most common forms of neuropathy are associated with sensory deficits in a glove-stocking distribution, but other patterns occur as well (Chapter 388).

When evaluating muscle strength, a distinction should be made between pain-induced and neurologic weakness (Chapter 366), with the latter often occurring in conjunction with muscle atrophy or asymmetric reflexes. Widespread physical findings such as diffuse tenderness or nonanatomic pain patterns may indicate central sensitization, opioid-induced hyperalgesia, a somatic symptom disorder, or another psychiatric illness (e.g., new-onset depression).

Psychologic Assessment

The lifetime prevalence of coexisting psychiatric illness in patients with chronic pain ranges from 50% to over 80%, and 30% to 60% of chronic pain sufferers experience symptoms of depression, anxiety, or posttraumatic stress (Chapter 362). These psychiatric conditions are strong predictors for the development of chronic pain after an episode of acute pain and are associated with poorer treatment outcomes. The clinician must screen all pain patients for psychological conditions that can adversely affect treatment (Table 26-3), including maladaptive behaviors and secondary diagnoses such as somatic symptom disorders and poor coping skills.

Diagnostic Tests

Imaging can be helpful in diagnosing the cause of pain, but it lacks specificity. For example, the correlation between findings on MRI and the intensity of spinal pain is modest at best, with more than 50% of asymptomatic individuals having abnormalities on lumbar, thoracic, and cervical films (Chapter 369). Musculoskeletal imaging should be reserved for patients who have serious or progressive deficits or "red flags," such as suspected malignancy, infection, or fractures.[8] For chronic pain disorders such as primary headaches, abdominal pain, or pelvic pain, imaging should be reserved for the evaluation of new-onset symptoms or a significant change in symptoms.

Electromyography and nerve conduction studies (Chapter 366) can diagnose injury to large nerve fibers. However, these studies are associated with both false-negative and false-positive results and are not sensitive for detecting impairment of small nerve fibers. For small-fiber neuropathies, a skin biopsy demonstrating decreased nerve fiber density can be valuable.

TABLE 26-3 PSYCHOSOCIAL FACTORS ASSOCIATED WITH CHRONIC PAIN

Multiple pain complaints
Poor job satisfaction/low pay
Inadequate coping skills, catastrophization
Fear-avoidance behavior
Manual labor/physically stressful job
Obesity
Somatization
Smoking
Low resiliency
Low baseline activity levels
Secondary gain (e.g., worker's compensation, ongoing litigation)
Older age
Low education level
High disease burden (e.g., pain intensity/disability, opioid use)
Substance misuse, including opioids
Neurologic symptoms
Anxiety
Depressed mood
Emotional distress

TREATMENT

In managing pain, realistic goals must be established, and individually tailored treatment regimens should be developed to achieve these ends. A key goal is to alleviate suffering, which can be the consequence of loss of physical function, social isolation, familial distress, and a sense of inadequacy.

Interdisciplinary pain programs can be more effective than unidimensional approaches and cost-effective when properly administered. The stepped care model recommends starting therapy with the least resource-intensive services and progressing to specialty care within a biopsychosocial framework. Within this paradigm, self-care can include weight loss if appropriate; a healthy lifestyle, including exercise[A1] and proper sleep hygiene; smoking cessation; and ergonomic modifications when indicated (Fig. 26-2). Whenever possible, nonopioid options are preferred.[9]

Pharmacologic Therapies

Antipyretic Analgesics

Acetaminophen, aspirin, and other nonsteroidal anti-inflammatory drugs (NSAIDs) form a cornerstone of pain pharmacotherapy (Table 26-4). These antipyretic analgesics exert their antinociceptive effects by inhibiting cyclooxygenase, the rate-limiting enzyme in the production of prostaglandins, which sensitize nociceptors and regulate inflammation. Whereas aspirin and NSAIDs act both centrally and peripherally, thereby making them effective topical agents for inflammatory conditions, acetaminophen is a weaker analgesic that acts primarily in the central nervous system (and possibly also via cannabinoid 1 and transient receptor potential cation channel subfamily V member 1 receptors) and is largely devoid of anti-inflammatory effects.

The main drawback of these nonopioid analgesics is their relatively limited therapeutic efficacy. Acetaminophen is often ineffective for spinal pain and usually provides only minimal, short-term benefit for knee or hip osteoarthritis.[A2] NSAIDs generally provide limited benefit for spinal pain and osteoarthritis compared with placebo.[A3]

A major concern for antipyretic agents is their side effects. For NSAIDs, these include bleeding, gastrointestinal ulceration, renal toxicity, and an increased risk of cardiovascular events. Cyclooxygenase-2 selective inhibitors such as celecoxib or the addition of a protein pump inhibitor (Table 124-1) may attenuate the risk of gastrointestinal bleeding, but the incidence of adverse renal or cardiovascular events remains increased, especially in patients who are elderly, have multiple comorbid conditions, and take many medications. In these and other situations, topical NSAIDs (e.g., diclofenac) can be useful for focal rheumatologic disorders, with fewer side effects.[A4]

Adjuvant Analgesics

For the treatment of neuropathic pain (Table 26-5), antidepressants and anticonvulsants (gabapentin and pregabalin) should be the two first-line classes of medications.[A5] Depending on the drug and condition, these medications can provide significant pain relief beyond that observed with placebo in 15% to 30% of patients with neuropathic pain, and may provide preemptive effects before surgery. In terms of efficacy, tricyclic antidepressants are superior to serotonin and norepinephrine reuptake inhibitors, which in turn are more efficacious

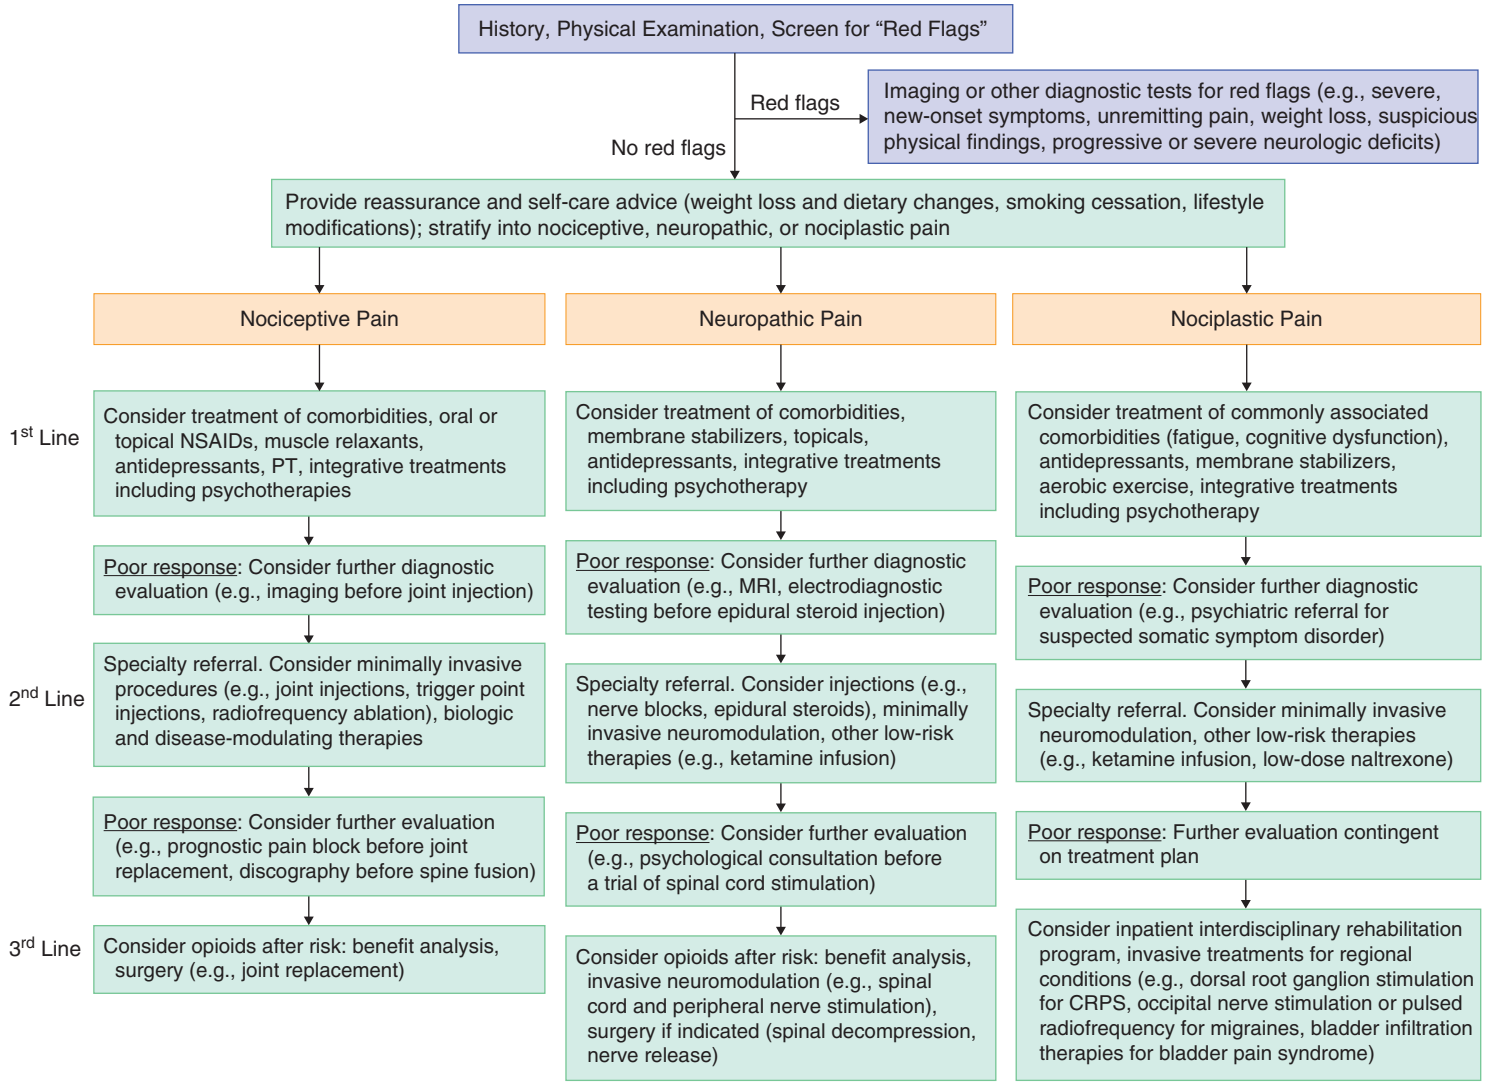

FIGURE 26-2. Approach to patient with chronic pain. CRPS = complex regional pain syndrome; MRI = magnetic resonance imaging; NSAIDs = nonsteroidal anti-inflammatory drugs; PT = physical therapy.

than serotonin specific reuptake inhibitors. Nortriptyline and imipramine have fewer side effects than amitriptyline and are preferable first-choice agents for neuropathic pain. Antidepressants are also effective for headaches (Chapter 367), nociplastic pain, and musculoskeletal disorders.

Although antidepressants are more versatile in that they have proven benefit in myriad pain conditions, gabapentin and pregabalin may be better than antidepressants for prototypical "lancinating-type" neuropathic pain. Gabapentin and pregabalin also act additively with antidepressants and opioids.[10]

When gabapentin and pregabalin are ineffective or intolerable, alternative anticonvulsants that act via different mechanisms may be tried. For trigeminal neuralgia (Chapter 367), carbamazepine remains the treatment of choice, though adverse effects such as agranulocytosis limit its utility. Other adjuvants that may be effective in certain contexts include topical agents such as lidocaine and capsaicin,[A6] NMDA antagonists (e.g., ketamine), and skeletal muscle relaxants/antispasticity drugs (e.g., baclofen).

Cannabinoids can treat chronic pain by binding to two receptors: CB1, which is expressed in high concentrations in the central nervous system (and is responsible for most of their euphoric effects) and along pain pathways, and CB2, which is found mainly on immune cells in peripheral tissue and contains anti-inflammatory properties.[11] FDA-approved cannabinoids are dronabinol, nabilone, and cannabidiol, none of which is currently approved for pain. Unfortunately, controlled trials have found that cannabinoids have limited benefit for chronic pain and a high rate of adverse effects.[A7] Nevertheless, some patients may benefit from their antiemetic and appetite-stimulating properties, as well as improved sleep and decreased anxiety. Serious side effects of cannabinoids may include cognitive and motivational impairment and psychological effects such as delusions, hallucinations, panic disorders, depression, and addiction.

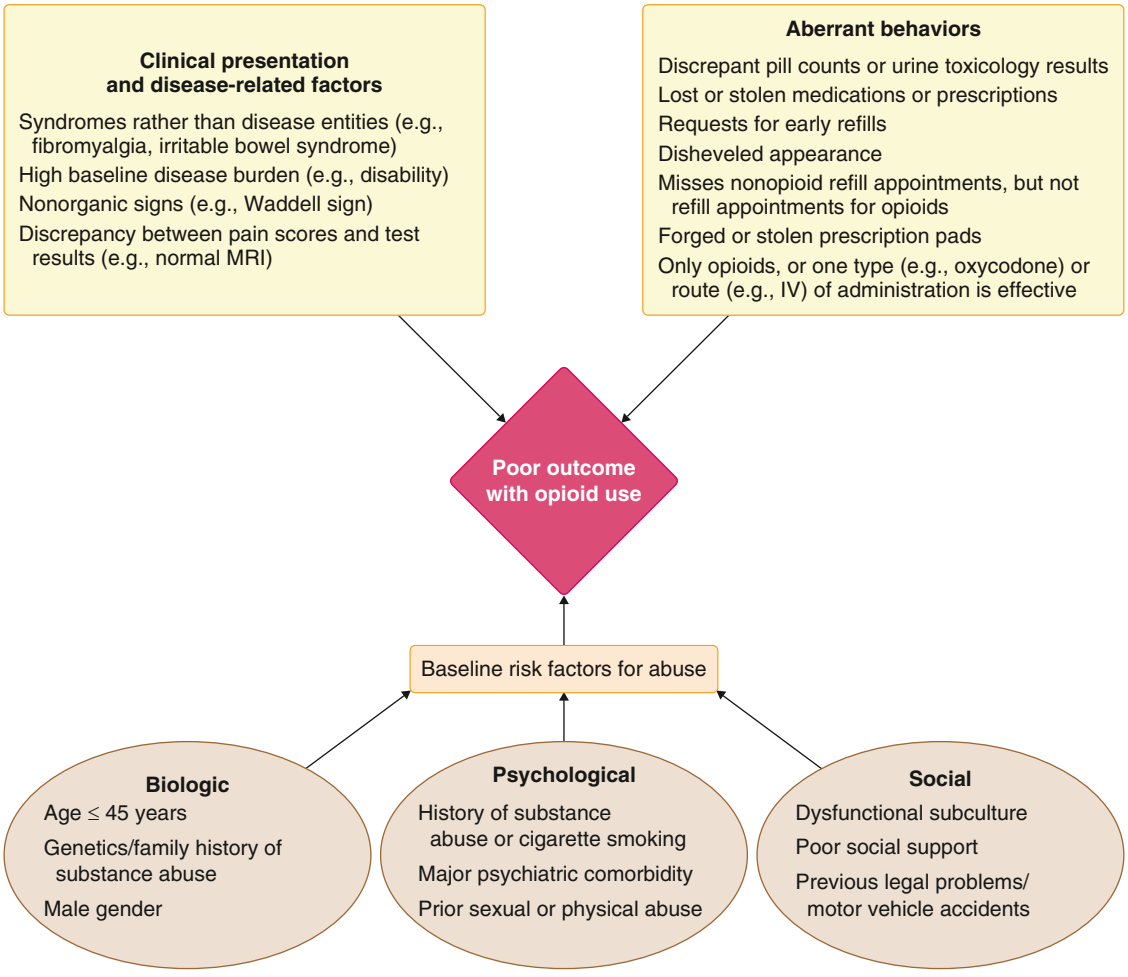
Opioid Analgesics

Opioid analgesics (Table 26-6) are a mainstay of treatment for cancer pain but are no longer considered first-line treatment for any noncancer pain because of limited evidence that they improve quality of life compared with nonopioid analgesics despite their abuse potential.[A8] For nociplastic pain, opioids may be less effective than for other pain categories, and some evidence actually supports the efficacy of opioid antagonists (e.g., low-dose naltrexone) for nociplastic pain.

Optimizing therapy with opioid analgesics requires carefully balancing the beneficial and undesirable effects (Table 26-7), including not only addiction but also nausea, constipation, sedation, itch, respiratory depression, and endocrine deficiency that leads to sexual dysfunction and accelerated osteoporosis.[12] Opioids that are predominantly eliminated by the kidneys, such as morphine, must be used with caution in patients with renal dysfunction; in this situation, alternatives include fentanyl and methadone.

The increasing use of prescription opioids for chronic pain has been associated with a dramatic increase in opioid-related deaths, a trend that has been amplified by the coronavirus disease 2019 (COVID-19) pandemic (Chapter 365). The long-term use of opioids can be associated with tolerance, hyperalgesia, physical dependence, and addiction. The rates of abuse and addiction, which vary substantially across studies, are heavily dependent on the population selected, surveillance, and differences in applying definitions. Rates of misuse are estimated at between 20% and 30%, and the incidence of addiction is less than 8% in carefully selected populations (E-Fig. 26-1). Sometimes the only way to distinguish between tolerance and opioid-induced hyperalgesia is with a long-term drug holiday. Cross-tolerance among opioids is incomplete, and a strategy often used to combat tolerance is opioid rotation, which may result in a 30% to 50% reduction in the equi-analgesic dose.

Tramadol and tapentadol represent a class of analgesic drugs that have dual mechanisms of action. Tramadol is a weak agonist that inhibits the reuptake of norepinephrine and serotonin. Along with the typical opioid-related side effects, seizures have been reported. Tapentadol, which is about twice as strong as tramadol, functions as a mu opioid agonist with a ceiling effect and as a norepinephrine reuptake inhibitor.



E-FIGURE 26-1. Factors associated with opioid abuse and/or treatment failure. IV = intravenous; MRI = magnetic resonance imaging.

TABLE 26-4 COMMONLY USED NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS)

DRUG SUBSTANCE	USUAL DOSE
OVER-THE-COUNTER	
Acetaminophen	325-650 mg orally q4-6h 650 mg q4h PRN IV or up to 1000 mg q6h PRN IV
Acetylsalicylic acid	325-650 mg orally q4-6h
Ibuprofen	200-800 orally q6-8h (200 mg available over-the-counter) 400-800 mg q6h IV PRN
Naproxen	220-550 mg orally q12h (220 mg available over-the-counter); extended release: 750-1000 mg orally q24h; 1500 mg orally may be given if well-tolerated
ORAL PRESCRIPTION	
Celecoxib (COX-2 selective)	100-200 mg orally q12-24h
Diclofenac	50 mg orally q8h 75 mg q24h IM
Diflunisal	Initial dose 500-1000 mg orally then 250-500 mg orally q8-12h
Etoricoxib (COX-2 selective; not available in United States)	30-90 mg orally daily
Etodolac (COX-2 selective)	300 mg orally q8-12h or 400-500 mg orally q12h; extended release 400-1000 mg orally q24h
Ketoprofen	25-50 mg orally q6-12h; extended release 100-200 mg orally daily
Ketorolac	Initial dose 20 mg orally, then 10 mg orally q4-6h 10-30 mg q4-6h IM or IV
Indomethacin	25-50 mg orally q6-8h; extended release 75 mg orally q12-24h
Mefenamic acid	Initial dose 500 mg orally, then 250 mg orally q6h, for up to 1 wk
Meloxicam (COX-2 selective)	5-15 mg orally in once or twice per day dosing 30 mg daily IV
Nabumetone (COX-2 selective)	1000-2000 mg orally daily
Oxaprozin	600-1200 mg orally daily
Piroxicam	Initial dose 40 mg orally, then 20 mg orally daily
Sulindac	150-200 mg orally q12h
TOPICAL CREAM	
Diclofenac	Apply up to 4 g q6h as needed; available over-the-counter in United States
Ketoprofen	Apply 2-4 g q6-12h as needed; not available in United States

h = hour; IM = intramuscular; IV = intravenous.

TABLE 26-5 RECOMMENDATIONS FOR THE PHARMACOLOGIC TREATMENT OF CHRONIC NEUROPATHIC PAIN

FIRST-LINE DRUGS/DRUG CLASSES	TYPICAL TOTAL DAILY DOSE AND REGIMEN
Gabapentin	1200–3600 mg, in three divided doses
Gabapentin extended release	1200–3600 mg, in one or two divided doses
Pregabalin	300–600 mg, in two divided doses
Duloxetine	60–120 mg, in one or two divided doses
Tricyclic antidepressants (e.g., nortriptyline, amitriptyline)	25–150 mg, usually once per day
SECOND-LINE DRUGS	
Capsaicin 8% patches (for peripheral neuropathic pain)	1-4 patches to the painful area for 30-60 min once every 3 mo
Lidocaine patches (for peripheral neuropathic pain)	1-3 patches to the region of pain once per day for up to 12 h
THIRD-LINE DRUGS AND THOSE RECOMMENDED IN SELECTIVE CIRCUMSTANCES	
Botulinum toxin A (subcutaneously)	50–200 units to the painful area once every 3 mo
Lamotrigine	200-400 mg in two divided doses
Carbamazepine	400-1200 mg in two divided doses
Oxcarbazepine	1200-2400 mg in two divided doses
Venlafaxine	150-225 mg in two or three divided doses
Ketamine (infusion)	No standard therapy for chronic pain in terms of rate or number of treatments, though higher cumulative doses (e.g., >400 mg) appear more effective
Baclofen (intrathecal, oral)	15-80 mg in three or four divided doses. Oral to intrathecal ratio 100 : 1
Tramadol, tapentadol, and pure mu-agonist opioids	See Table 26-6

All medications are oral unless otherwise indicated.

Recommendations based on Schlereth T. Guideline "diagnosis and non interventional therapy of neuropathic pain" of the German Society of Neurology (Deutsche Gesellschaft für Neurologie). *Neurol Res Pract*. 2020;2:16.

Butorphanol, nalbuphine, and pentazocine are opioid agonist-antagonist drugs. These drugs should be used with caution, particularly in patients who are receiving other opioid agonists, because they may precipitate withdrawal or reduce the effectiveness of pure opioid agonists. Buprenorphine, which is a long-acting partial agonist at the mu opioid receptor and an antagonist at other opioid receptors, is available in various formulations as a stand-alone analgesic and in combination with naloxone for treatment of opioid addiction.

Combination Pharmacotherapies

Guidelines suggest that when monotherapy is ineffective, multiple agents that act at different sites and ideally have antagonistic adverse effects may be combined (E-Fig. 26-2). Controlled trials have found that gabapentin plus nortriptyline, gabapentin plus morphine, nortriptyline plus morphine, and mirtazapine plus pregabalin provide superior benefit than either drug alone for neuropathic pain.[A9]

Psychologic Treatment

Relaxation techniques such as biofeedback and guided imagery are effective for a wide array of acute and chronic pain conditions but may be especially useful in individuals with high levels of anxiety. Cognitive-behavioral therapy, which is a structured form of psychotherapy predicated on the replacement of negative thought patterns and behaviors with more constructive ones, enhances inhibitory pain signals and also can be effective for associated symptoms such as fatigue and insomnia.[A10,A11] Ideal candidates include motivated patients in whom distorted thinking (e.g., catastrophization) and counterproductive behaviors (e.g., fear-avoidance) amplify pain. In patients with personality disorders and ingrained maladaptive behaviors, which may also predispose to pain and pain-related disability, long-term psychotherapy may be necessary.

Physical Treatments

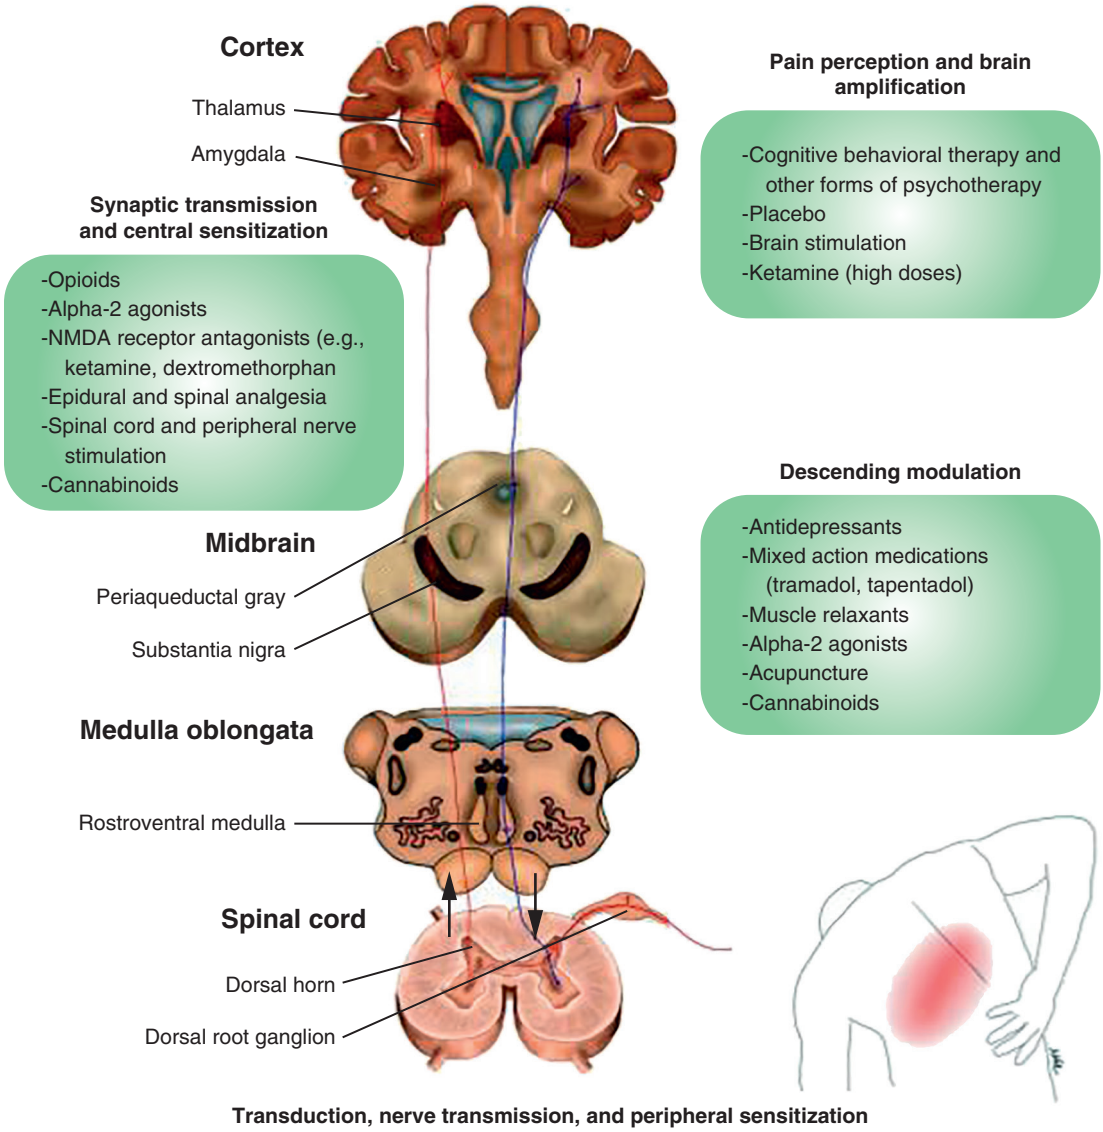
The use of physical therapies to provide pain relief and enhance function is a cornerstone of integrative treatment. Physical therapists evaluate, educate, and provide minimally invasive procedural interventions to help prevent and alleviate pain and dysfunction. These interventions include addressing causes of pain (e.g., correcting gait abnormalities) and providing treatments (e.g., hot and cold packs, joint manipulation).

Exercise is an effective treatment for many forms of chronic pain, and it also is a means to prevent injury. Exercise reduces the sensitivity to pain but is more beneficial for improving function than for relieving pain and more beneficial for musculoskeletal and diffuse pain than for neuropathic pain.[A12]

Interventional therapies

Local Injections and Nerve Blocks

Local injections of lidocaine may be tried for diagnostic, therapeutic, and prognostic purposes. In appropriate patients (especially trigger point injections for myofascial pain, intra-articular injections for osteoarthritis, and nerve blocks with corticosteroids for nerve entrapment syndromes), injections can provide intermediate-term pain relief, facilitate rehabilitation, and improve quality of life. For radicular leg pain, spinal injections can provide limited benefit.[A13] Patients



E-FIGURE 26-2. **Rational choice of pharmacologic therapies for pain should be based on the mechanisms of drug actions.** Combining drugs with disparate sites of action can have additive or synergistic analgesic effects and minimize adverse effects. NMDA = N-methyl-D-aspartate. (Drawing courtesy of Seffrah Cohen.)

TABLE 26-6 FORMULATIONS, DOSAGES, AND PHARMACOLOGIC INFORMATION ON COMMONLY PRESCRIBED OPIOIDS

PURE OPIOID AGONISTS

DRUG	EQUIANALGESIC DOSAGE (ORAL UNLESS SPECIFIED)	READILY AVAILABLE ROUTES OF ADMINISTRATION	DURATION OF ACTION	COMMENTS
Morphine	30 mg	IV, IM, PO, PR; SR formulation	3-6 h for short-acting, 8-12 h for SR	Reference standard for all opioids. Renally excreted active metabolite
Oxycodone	20 mg	PO, PR; SR formulation	3-6 h for short-acting, 8-12 h for SR	Widely available in combination form with nonopioid analgesics. Greater euphoric effects than morphine. Popular among recreational users
Hydromorphone	3-6 mg	PO, PR, IV, IM, SR formulation	3-6 h, 18-24 h for SR	Higher PO: IV conversion ratio than other opioids. SR form reserved for opioid-tolerant patients, and contraindicated in patients with recent monoamine oxidase inhibitor use
Hydrocodone	30-60 mg	PO, SR formulation	3-6 h, 12-24 h for SR	Wide variation in morphine equivalent dose. Most commonly prescribed opioid in United States. Typically used in combination form with nonopioid analgesic acetaminophen. IR products containing <15 mg hydrocodone are Schedule III in the United States. SR form available without acetaminophen
Oxymorphone	10 mg	PO, IV, IM, PR; SR formulation	4-8 h, 8-12 h for SR	Coingestion of alcohol with SR formulation can lead to rapid increase in plasma levels and overdose. Very low (10%) oral bioavailability
Methadone	2-10 mg (see comments)	PO, PR, IV	6-12 h for pain	Morphine: methadone conversion varies according to dose and length of opioid use, ranging from 3 : 1 to > 20 : 1 in patients on very high doses. Any physician with a Schedule II DEA license may prescribe for pain. May take 5-7 days to reach steady state due to long half-life. ECG monitoring recommended with higher doses. Other properties such as NMDA receptor antagonism and reuptake inhibition of serotonin and norepinephrine may slow tolerance and increase efficacy for neuropathic pain
Levorphanol	3 mg	PO, IM, IV	4-10 h	2 : 1 oral to IV conversion ratio. Agonist at mu, kappa, and delta receptors. Multiple mechanisms of action, including inhibition of serotonin and norepinephrine reuptake, NDMA receptor antagonism and sigma receptor agonism. Long half-life exceeded only by methadone
Fentanyl	12.5 µg/h (TD) = 30 morphine milliequivalents/day Dosing 100-1200 µg for TM Potency for TM formulations varies from 1/8 that of morphine for buccal or sublingual tablets or lozenges to 1/5 for films or oral sprays	TD, TM	72 h for TD; 1.5-3 h for TM	TD and TM formulations may be useful in patients with poor bowel function. Rapid onset (<10 min) iontophoretic TD system available for postoperative pain TD: Wide variation in conversion ratios and doses depending on route. Delivery system may be associated with fewer gastrointestinal side effects, and include buccal, sublingual, and intranasal routes TM delivery associated with more rapid (10 min) onset than immediate-release oral opioids. FDA approved for breakthrough cancer pain in opioid-tolerant patients
Sufentanil	15-30 µg (~7.5 times as potent as fentanyl)	TM	1-3 h	Rapid onset, wide variation in conversion ratio. For use only in health care and battlefield settings. 15 and 30 µg dosages approved in Europe and United States. Not approved for home use or for longer than 72 h
Propoxyphene	200 mg	PO, PR	3-6 h	Removed from market in United States. Wide variation in morphine equivalent dose. Often used in combination form with nonopioid analgesics. Toxic metabolite may accumulate with excessive use, especially in elderly. Weak antagonist at NMDA receptor
Meperidine	300 mg	PO, PR, IM, IV	2-4 h	Toxic metabolite may accumulate with excessive use, especially in patients with renal insufficiency. Associated with tachycardia and hypertension. Concurrent use with monoamine oxidase inhibitors may result in fatal reactions. May cause more "euphoria" than other opioids. IM absorption erratic

TABLE 26-6 FORMULATIONS, DOSAGES, AND PHARMACOLOGIC INFORMATION ON COMMONLY PRESCRIBED OPIOIDS—cont'd

DRUG	TYPICAL DOSING/ ANALGESIC POTENCY	READILY AVAILABLE ROUTES OF ADMINISTRATION	DURATION OF ACTION	COMMENTS
AGONIST-ANTAGONISTS, PARTIAL AGONISTS				
Buprenorphine Buprenorphine/ Naloxone (4 : 1 ratio for opioid addiction)	0.3-24 mg SL 5-70 µg/h (TD) 2-24 mg/day (tablets and films about 30 times as potent as morphine; TD patch 10-15 times as potent)	TM, PR, IV, TD	8-12 h for TM, 7 days for SR, once daily for stable buprenorphine/ naloxone combination	Partial mu agonist and kappa antagonist that may precipitate withdrawal in opioid-dependent patients on high doses. Lower abuse potential and fewer side effects than pure agonists. Not readily reversed by naloxone. Schedule III drug in United States. Primarily used in combination with naloxone as sublingual or buccal tablets and films for opioid dependence. May prolong QT interval
Butorphanol	1 mg/spray, repeat after 60-90min (IN) 1-2 mg (IV/IM) (~7 times as potent as morphine)	IN, IM, IV, PO	3-5 h	Mixed agonist-antagonist at mu receptor and antagonist at kappa receptor. Commonly used as nasal spray to treat migraine headache, and less commonly for labor pain. Significant abuse potential
Nalbuphine	1 : 1 parenteral analgesic potency ratio to morphine (~0.8 : 1.0 [equianalgesic] times as potent as morphine)	SQ, IM, IV	3-6 h	Mixed agonist-antagonist, often used for labor and delivery. Sometimes used to treat refractory opioid-induced pruritus
Pentazocine Pentazocine/ Naloxone (Talwin) (100 : 1 ratio of pentazocine to naloxone)	90 mg (~3 times as potent as morphine)	PO, SQ, IM, IV	3-4 h parenteral, 3-8 h PO	Mixed agonist-antagonist. (–) enantiomer is kappa agonist. Naloxone added in 1970s (Talwin) to prevent abuse. Commonly prescribed in preparation with acetaminophen
WEAK, DUAL-ACTION OPIOID AGONISTS				
Tramadol	50-100 mg, up to 400 mg/day (1/10th as potent as morphine)	PO	4-6 h, 24 h for SR	Dual action involves inhibition of serotonin and norepinephrine reuptake. Affinity for mu opioid receptor 6000× less than morphine. Analogue of codeine with active metabolite in which differences in metabolism may influence drug effects. Available in combination form with acetaminophen. Maximum recommended dose of 400 mg/day. Avoid concurrent use of monoamine oxidase inhibitors. Recently moved to FDA category Schedule IV in United States
Tapentadol	50-100 mg, up to 600 mg/day (⅓ to ⅔ as potent as morphine)	PO	4-6 h, 12 h for SR	Dual action involves inhibition of norepinephrine reuptake. May have fewer of certain side effects than morphine, such as gastrointestinal and respiratory depression. Maximum dose 600 mg/day. Avoid concurrent use of monoamine oxidase inhibitors. Schedule II in United States. Approved for diabetic neuropathy

DEA = Drug Enforcement Administration; ECG = electrocardiogram; FDA = U.S. Food and Drug Administration; IM = intramuscular; IN = intranasal; IR = immediate release; IV = intravenous; NMDA = N-methyl-D-aspartate; PO = oral; PR = rectal; SL = sublingual; SR = sustained release; TD = transdermal; TM = transmucosal.

who have concomitant psychosocial issues (e.g., secondary gain, untreated depression) or a greater burden of disease, are taking opioids, and have a discordance between their symptoms and the findings on physical examination or imaging are unlikely to benefit. Although the theoretical benefits of adding a corticosteroid to lidocaine include blocking the inflammatory cascade (thereby suppressing ectopic discharges from injured nerves and inhibiting the synthesis of prostaglandins), the incremental benefit of adding corticosteroids to a local anesthetic for nerve blocks or to epidural or joint injections is small.[A14] In patients who benefit from local injections, translating the temporary relief into long-term improvement necessitates addressing the underlying cause, which often requires rehabilitation and psychotherapy.

Biologic therapies such as bone marrow concentrate and platelet-rich plasma have shown inconsistent results in the treatment of musculoskeletal disorders and peripheral nerve injuries.[A15] In patients with lumbar facet joint pain, sacroiliac joint pain, or knee osteoarthritis, evidence supporting radiofrequency denervation is mixed.[13] In patients with cancer pain, neurolytic procedures targeting the celiac plexus for upper abdominal pain and the superior hypogastric plexus for pelvic pain may provide significant benefit lasting several months.

Electrical Stimulation

The most common form of electrical stimulation[14] is transcutaneous electrical nerve stimulation. The evidence supporting transcutaneous electrical nerve stimulation to treat chronic pain is mixed, with evidence of limited, short-term benefit for neuropathic pain[A16] but not for back pain. Spinal cord stimulation is a neuromodulatory technique in which an electrode is inserted epidurally to stimulate the dorsal column. Conventional, high-frequency, and burst stimulation have all been shown to be effective for chronic pain, with mixed evidence supporting one modality over another. The strongest evidence for spinal cord stimulation is to treat complex regional pain syndrome, ischemic pain, and back pain with predominantly radicular pain after unsuccessful back surgery.

Peripheral nerve stimulation is used for patients with neuropathic pain in the distribution of one or two nerves and for headaches (Chapter 367), with relief sometimes persisting for more than 1 year for neuropathic pain but mixed evidence for efficacy in migraine headaches.[15] In patients with intractable chronic pain unresponsive to conservative measures, deep brain and motor cortex stimulation may be considered, with the strongest evidence for neuropathic pain.

Surgery

Surgical interventions are often advocated in patients who have failed conservative measures. A traumatic neuroma is an inexorable consequence of cutting or burning a nerve, formed as a result of unregulated and disorganized nerve regeneration. Neuromas have been shown to fire ectopic pain signals and are often quite painful. Hence, neurolytic procedures are rarely successful in the

TABLE 26-7 GUIDELINES FOR OPIOID THERAPY

1. Nonpharmacologic and nonopioid pharmacologic therapy are preferred for subacute and chronic pain and should be used before initiating opioid therapy. For acute pain, consider opioid therapy only if the benefits are anticipated to outweigh the risks.
2. Establish realistic goals before starting opioid therapy and discuss how therapy will be discontinued.
3. Before starting opioids and during treatment, risk factors for harm should be evaluated, and strategies to mitigate risk (e.g., offering naloxone) should be incorporated in patients who are at risk of overdose.
4. Initiate therapy with immediate-release opioids.
5. Start with the lowest effective dose; carefully reassess benefits and risks when dosage is increased. Avoid increasing doses to levels likely to yield diminishing benefits relative to risks.
6. For patients who are already receiving higher opioid dosages, clinicians should carefully weigh benefits and risks and exercise care when reducing or continuing the opioid dosage. If risks outweigh benefits of continued opioid therapy, clinicians should optimize other therapies and work closely with patients to taper to lower dosages gradually or, if warranted, appropriately taper and discontinue opioids. In the absence of life-threatening or extenuating circumstances, opioid therapy should not be discontinued abruptly, and clinicians should not abruptly or rapidly reduce opioid dosages.
7. For the treatment of acute pain, clinicians should prescribe no greater quantity than needed for the expected duration of pain severe enough to require opioids.
8. Evaluate the patient within 1 to 4 weeks after starting opioids, and reevaluate the benefits and harms within 3 months or more frequently as indicated.
9. When prescribing opioids for acute, subacute, or chronic pain, review the patient's history of use of controlled substance with a prescription drug monitoring program.
10. When prescribing opioids for subacute or chronic pain, consider toxicology testing to assess for prescribed medications as well as other prescribed and nonprescribed controlled substances.
11. Clinicians should use extreme caution when prescribing opioids and benzodiazepines concurrently and consider whether the benefits outweigh risks when concurrently prescribing opioids and other central nervous system depressants.
12. For patients with opioid use disorder (Chapter 365), offer or arrange treatment with medications (e.g., buprenorphine or methadone).

Adapted from Dowell D, Ragan KR, Jones CM, Baldwin GT, Chou R. CDC guideline for prescribing opioids—United States, 2022. Available at https://www.cdc.gov/mmwr/volumes/71/rr/pdfs/rr7103a1-H.pdf.

long-term treatment of neuropathic pain. Total joint replacement (Chapter 255) is an increasingly common treatment for osteoarthritis of the knee or hip, but up to 40% of patients will experience significant pain following arthroplasty. Surgery done solely to remove a painful body part (e.g., orchiectomy, limb amputation) rarely results in long-term benefit.

Complementary and Alternative Therapies

Pain is the most common indication for complementary and alternative medical treatments (Chapter 30), with utilization rates approaching 40%. Some of the most popular modalities are acupuncture, chiropractic, nutraceuticals, Tai Chi, and yoga, all of which are beneficial in certain contexts. However, the magnitude of benefit tends to be modest, and little evidence supports one modality over another or against conventional medical treatments. Other supplements that have been used to treat chronic pain include omega-3 polyunsaturated fatty acids, natural eggshell membrane, turmeric, ginger, magnesium, and vitamin B_{12}.

Back Pain

In many populations, back pain is the leading cause of pain worldwide. Careful diagnostic assessment is required. For pain that has a clear anatomic cause and does not respond to medications, physical therapy, injections, and surgery may all be considered (Chapter 369).[A17]

Pain Management in Vulnerable Populations

Persons at particularly high risk for chronic pain include individuals with intellectual disabilities, older adults, indigent people, and torture survivors.[16] For these vulnerable populations, focus should be on the utilization of tools to assess pain and monitor treatment compatible with cognitive abilities, adapting therapy to individual circumstances, understanding age-related differences in drug pharmacokinetics, and ensuring autonomy and dignity.

Older adults have higher pain thresholds and lower pain tolerance; they are more likely to report pain, often with multiple comorbid conditions, than are younger adults. The increased risk for drug-related adverse effects in this population is the basis for the popular recommendation, "start low and go slow" in the titration of drugs. Age-related physiologic factors that can decrease the therapeutic dose of opioid and nonopioid analgesics include changes in volume of distribution and protein binding, decreased metabolism, decreased excretion, and increased pharmacologic sensitivity. Thus, nonpharmacologic interventions such as ergonomic modifications, tailored physical therapy and exercise programs, nutritional consultation, psychobehavioral approaches, and injections should be considered in appropriate patients.[17]

FUTURE DEVELOPMENTS

Research is addressing the genotyping and phenotyping of chronic pain patients both to identify individuals at high risk for chronification of pain and to guide treatment. Neuroimaging and molecular biomarkers may, in the future, help to measure nociception and pain, and also function as objective indicators of treatment response.

Regenerative therapies (Chapter 34) seek to facilitate the body's ability to repair, replace, restore, and/or regenerate diseased or damaged tissue. Some treatments, such as platelet-rich plasma, are commonly used to treat musculoskeletal conditions with mixed results. Others, such as stem cell therapy, are also being investigated for nerve injury and degenerative conditions. The approach to managing pain must consider the reality of spiraling health care costs and opioid addiction (Chapter 365).

27 BIOLOGY OF ADDICTION

ERIC J. NESTLER

DEFINITION

Drug addiction involves compulsive substance use despite serious negative consequences. Harmful drug use and addiction are significant contributors to medical morbidity and mortality both directly as a result of the toxic effects of abused drugs and indirectly through accidents, violence, nonsterile needle use, smoking, and other health hazards. By far the greatest contributors to illness and death are the widely used legal drugs, tobacco (Chapter 363) and alcohol (Chapter 364), although illegal addictive drugs and abused prescription drugs also exact a significant toll. An increasing impact of cannabinoids is expected as legal restrictions against such drugs are eased and their use increases. In addition, addiction creates enormous burdens on society by impairing the function of the addicted person in multiple life roles, disrupting families and neighborhoods, and motivating crime.

Compulsive use, the cardinal feature of addiction, means that the affected person cannot control substance use for a significant period of time despite powerful reasons to do so, such as drug-related health problems, drug-associated arrests, or the threat of losing one's job or spouse.[1] In the outpatient setting, addiction can be remarkably frustrating to treat: drug seeking and administration are apparently voluntary behaviors that an otherwise sentient person seems unwilling to control. Even after significant efforts have been exerted to get an addicted patient into drug treatment, relapse is common, even long after the last withdrawal symptom has cleared. Relapses are often precipitated by stress or by reminders of drug use (cues) that may range from familiar drug use contexts (such as smoking after a meal) to interactions with drug-using friends, the smell of marijuana or tobacco smoke, and body feelings previously associated with drug seeking (so-called interoceptive cues).

Drug users may repeatedly take drugs to gain pleasure or to escape from negative feelings, including the aversive feelings that may occur when drugs wear off.[2,3] As a result of repeated drug administration over time, initial protein targets for the drugs and their downstream signaling pathways (Table 27-1) are excessively stimulated and may thus undergo homeostatic adaptations. These adaptations can produce tolerance (the need for increasing drug doses to achieve desired affects) or dependence (revealed by withdrawal symptoms between drug doses or with drug cessation). Both tolerance and dependence can contribute to ongoing drug use and to dosage increases; however, neither tolerance nor dependence alone explains compulsive use. First, tolerance and dependence occur not only with repeated use of many addictive drugs (e.g., heroin, alcohol) but also with many nonaddictive drugs (e.g., β-adrenergic antagonists, α_2-adrenergic agonist antihypertensive agents, nitrates, selective serotonin reuptake inhibitor antidepressants). Second, some highly addictive drugs, such as cocaine, may produce little physical dependence and withdrawal in some individuals who nonetheless exhibit compulsive use. Finally, if dependence and withdrawal were necessary factors in addiction, the phenomenon of late, post-detoxification relapse would not be the major clinical problem that it is. Although these forms of homeostatic adaptation play a role in addiction, other types of plasticity within the nervous system are more significant.

RISK FACTORS FOR ADDICTION

Only a minority of individuals who use drugs go on to become addicted. The best-established risk factors for addiction are male sex and family history. Across countries and cultures, males have a greater risk for both heavy drug use and addiction, with risk ratios in the range of 1.4:1 to 2:1, but the sex ratios have narrowed in many countries, especially for tobacco use and alcohol. Moreover, females who succumb to addiction tend to do so more quickly after initial drug exposures, and drug use during pregnancy can have enormously deleterious effects on the fetus.[4]

Genes play a major role in familial risk as evidenced by twin and adoption studies. Twin studies consistently show higher rates of concordance for heavy drug use and addiction within monozygotic twin pairs than within dizygotic twin pairs. Adoption studies demonstrate that individuals adopted early in life tend to resemble their biologic rather than their adoptive parents with respect to patterns of alcohol use. Large population genetic studies suggest that the heritable risk for addiction to any of several substances, including opioids, stimulants, nicotine, alcohol, and marijuana, is roughly the same and varies between 30 and 60%, depending on the study. Adverse life events (e.g., stress, trauma) are important noninherited factors that also determine an individual's risk for addiction.

Although genes clearly play a significant role in vulnerability to addiction, only a small portion (<10%) of the specific genetic variants that confer risk have been identified with certainty. Like all common neuropsychiatric disorders, addiction risk is highly genetically complex; there is evidence from linkage and association studies for contributions by many hundreds of genetic variants, each with a very small effect.[5–7] The strongest genetic risk factors identified to date are variations in genes that encode acute drug targets, such as nicotinic cholinergic receptor subunits, although each contributes only a very small portion of the overall heritable risk. However, the task of gene identification is complicated by the challenges of phenotype definition. There are no objective medical tests with which to make the diagnosis, and there may be independent genetic and nongenetic risk factors for different stages of substance use disorders, such as drug experimentation, addiction, and treatment responsiveness. Moreover, twin and family studies suggest that there may be both shared and unshared genetic risk factors as well as epigenetic changes[8] underlying addictions to different drugs. As in other genetically complex disorders, it is hoped that with the identification of numerous risk-conferring variants, it will be possible to identify key biochemical pathways involved in addiction pathogenesis, which will then suggest potential targets for new and more effective treatments.

REWARD CIRCUITRY: THE NEURAL SUBSTRATE OF ADDICTION

The survival and perpetuation of species require that animals, including humans, learn to predict threats and also learn the circumstances under which they can

TABLE 27-1 PROPERTIES OF ADDICTIVE DRUGS

DRUG	NEUROTRANSMITTER	DRUG TARGET	EFFECT AFTER BINDING
Opioids (morphine, heroin, oxycodone, fentanyl)	Endorphins; enkephalins	μ and δ opioid receptor (agonist)	Activate G_i/G_o; activate K^+ channels
Psychostimulants (cocaine, amphetamines)	Dopamine (DA)	Dopamine transporter (DAT)* (antagonist)	Increase synaptic DA; stimulate presynaptic and postsynaptic DA receptors
Nicotine	Acetylcholine	Nicotinic acetylcholine receptor (nAChR) (agonist)	Stimulate cation channel (may desensitize)
Alcohol†	γ-Aminobutyric acid (GABA) Glutamate	$GABA_A$ receptor (agonist) *N*-methyl-D-aspartate (NMDA) receptor (antagonist)	Activate Cl^- channel Inhibit Na^+/Ca^{2+} entry
Marijuana (Δ^9-tetrahydrocannabinol)	Anandamide; 2-arachidonoylglycerol	Cannabinoid CB_1 (agonist)	Activate G_i/G_o; activate K^+ channels
Phencyclidine, ketamine	Glutamate	NMDA receptor (antagonist)	Inhibit Na^+/Ca^{2+} entry

*The psychostimulants also interact with the norepinephrine and serotonin transporters, but under normal conditions, it is the DAT that is critical for rewarding and addictive properties. Unlike cocaine, amphetamines enter dopamine nerve terminals through the DAT and interact with a second target, the vesicular monoamine transporter (VMAT), to release DA into the cytoplasm and thence, through the DAT, to release it into the synapse.

†Alcohol binds to and affects many other protein targets (e.g., several types of ion channels) that also contribute to its overall actions.

Modified from Hyman SE, Malenka RC, Nestler EJ. Neural mechanisms of addiction: the role of reward-related learning and memory. *Annu Rev Neurosci*. 2006;29:565-598.

ABSTRACT

Only a minute fraction of the approximately billion compounds known in chemical space share the property of inducing addiction: compulsive drug intake despite adverse consequences. Such compounds are termed drugs of abuse. Despite their very different chemical structures and very different initial protein targets in the brain, all drugs of abuse converge on the brain's reward circuity, which evolved to regulate responses to natural rewards in the environment such as food, sex, and social interaction. This convergent action includes increasing dopaminergic neurotransmission from the midbrain ventral tegmental area to the nucleus accumbens and other regions of the forebrain, as well as the activation of several other reward-related neurotransmitter systems. Repeated exposure to drugs of abuse, with repeated activation of these acute reward mechanisms, induces pathologic changes in individual reward neurons and associated glial cells, as well as in the functioning of the overall brain reward circuitry. These effects then drive an individual's compulsive drug use. The ability of a drug to induce such changes, and therefore addiction, is highly heritable, with about 50% of the risk being genetic, apparently via hundreds of specific genes.

obtain "rewards," such as food, water, shelter, and opportunities for mating. A simple operational definition of reward is a stimulus that elicits approach and consummatory behaviors. Several interconnected neural circuits, highly conserved in evolution, control an individual's responses to rewarding and aversive stimuli (E-Fig. 27-1). Dopamine-releasing neurons in the ventral tegmental area of the midbrain and their major target neurons in the nucleus accumbens in the ventral striatum serve as a rheostat that detects and drives responses to rewards and threats. The amygdala and hippocampus are crucial for forming reward- and fear-related memories. The dorsal striatum (caudate and putamen) mediates well-learned behaviors and habits. Finally, several regions of the prefrontal cortex exert executive control over these subcortical systems. Addiction involves abnormal functioning of this entire circuit.[9,10]

The neurotransmitter dopamine, released from ventral tegmental area nerve terminals in the nucleus accumbens, plays the key (albeit not the only) role in binding rewards and reward-associated cues to adaptive reward-seeking responses. In animals, implanted electrodes can record firing of dopamine neurons; microdialysis catheters and electrochemical methods can be used to detect dopamine that has been released from presynaptic terminals. In humans, positron emission tomography (PET) permits indirect measures of dopamine release by observing the displacement of a positron-emitting D_2 dopamine receptor ligand previously bound to receptors after a stimulus or pharmacologic challenge. Such methods show that natural rewards cause firing of neurons in the ventral tegmental area and release of dopamine in the nucleus accumbens and other forebrain regions. When dopamine action does not occur because of lesions in dopamine neurons, blockade of postsynaptic dopamine receptors, or inhibition of dopamine synthesis, rewards no longer motivate the behaviors necessary to obtain them.

The role of dopamine has been elucidated in patients with Parkinson disease (Chapter 378), which results from the death of midbrain dopamine neurons; however, neurons within the substantia nigra, which project to the dorsal striatum, are more severely affected than neurons within the ventral tegmental area. Patients are generally treated with l-dopa, a dopamine precursor, but as the disease progresses, other drugs may be needed, including selective D_2 dopamine receptor agonists. A minority of patients treated with these D_2 dopamine receptor agonists develop new risky, goal-directed behaviors, such as compulsive gambling or shopping. These behaviors generally cease when the D_2 dopamine receptor agonist is withdrawn, presumably because these agents can combine with endogenous dopamine from preserved neurons in the ventral tegmental area to overstimulate the nucleus accumbens and other components of the reward circuitry. These observations not only underscore the role of dopamine in motivation and reward seeking but also suggest that behavioral addictions share neural substrates with drug addiction.[11,12]

The precise pattern of firing of dopamine neurons and the resulting synaptic release of dopamine in forebrain circuits shape behavior so as to maximize future reward. In a basal state, dopamine neurons have a slow tonic pattern of firing. When a new, unexpected, or greater-than-expected reward is encountered, a phasic burst of firing of dopamine neurons causes a transient increase in synaptic dopamine. When a reward is predicted from known cues and is exactly as expected, there is little change from the tonic pattern of firing, that is, only small additional dopamine release. When a predicted reward is omitted or less than expected, dopamine neurons pause their firing to levels below their tonic rate. Phasic increases in synaptic dopamine signify that the world is better than expected, facilitate learning of new predictive information, and bind the newly learned predictive cues to action.

Dopamine is not the only neurotransmitter that signals reward. Other neurotransmitters, including acetylcholine, endogenous opioid peptides (e.g., enkephalin and endorphin), and endogenous lipid substances called endocannabinoids (because cannabinoid drugs like marijuana are agonists at their receptors), are also released in the reward circuitry in response to natural rewards.

PROPERTIES OF ADDICTIVE DRUGS

Addictive drugs are chemically diverse, and these interact with different molecular targets in the nervous system (Table 27-1). They also exhibit significant differences from each other in many of their physiologic and behavioral effects.[13–15] For example, cocaine and amphetamines are stimulants that increase arousal, may cause anxiety, and at lower doses enhance cognitive performance. Alcohol, which is a depressant, is anxiolytic at low doses and degrades cognitive performance. Heroin and other opioids, which are analgesic, cause drowsiness, constipation, and pupillary constriction. The shared behavioral effect of all addictive drugs is the liability, in vulnerable individuals, of causing compulsive use. The shared pharmacologic property that is a major mediator of addiction is the ability to increase levels of synaptic dopamine in the nucleus accumbens and other regions of the forebrain. For example, cocaine blocks the dopamine uptake transporter that normally clears dopamine from synapses. Amphetamines cause reverse transport of dopamine into synapses through the dopamine uptake transporter. Opioids, nicotine, cannabinoids, and alcohol cause dopamine release, and they act by different initial mechanisms to stimulate dopamine neurons in the ventral tegmental area or to release them from resting inhibitory control. The first three of these drugs also induce reward through nondopamine mechanisms (i.e., by activating cholinergic, opioid, or cannabinoid receptors). By comparison, alcohol directly affects γ-aminobutyric acid and glutamate receptors within the reward circuitry (Table 27-1).

Natural rewards, such as food or sexual opportunities, regulate the firing of dopamine neurons through highly processed sensory information, both external and interoceptive. Addictive drugs short-circuit this kind of information processing by acting directly on proteins that control dopamine and other signals in the reward circuitry. Acting by such direct pharmacologic mechanisms, addictive drugs typically produce greater quantities of synaptic dopamine and other reward-related neurotransmitters over longer times compared with natural rewards. In addition, addictive drugs provide a grossly pathologic learning signal by occluding pauses in dopamine and other neuron firing, even when drug use proves less pleasurable than expected or even aversive. For example, when the inhalation of smoke causes painful coughing, it might seem that the brain would signal an experience that is worse than expected with a resulting decrement in the firing rate of neurons in the ventral tegmental area. However, because nicotine causes dopamine release pharmacologically, independent of the smoker's actual experience, reward circuits, unavailable to conscious introspection, still receive a positive message that reinforces nicotine-seeking and nicotine use. In short, addictive drugs, by virtue of their effects on dopamine and related neurotransmitters, always signal "better than expected."

DRUG-INDUCED NEURAL PLASTICITY RELEVANT TO ADDICTION

Neurobiologic research on addiction has focused intensely on compulsive aspects of drug use, the ability of specific cues to activate drug seeking and craving, and the long persistence of stress- and cue-dependent relapse risk. As described previously, compulsive drug use and the power of drug-associated cues reflect the usurpation of the brain's reward circuitry by drugs of abuse. The persistence of addiction reflects long-term changes in neurons and synapses, as well as their interacting circuits. These long-lived alterations in gene expression can be attributed to drug-induced epigenetic mechanisms, such as modifications of chromatin.[16]

Long-term changes in gene expression may render the addicted person susceptible to stress and may also create persistent changes in hedonic state and mood regulation that may motivate drug taking. By themselves, however, changes in gene expression do not explain the ability of exquisitely specific cues to activate drug seeking or, if seeking is impeded, intense subjective drug craving. The ability of specific cues to activate drug seeking and wanting is based on long-term associative memories consolidated under the influence of dopamine and other reward signals, in part via changes in gene expression.[17,18] Long-term memory formation represents perhaps the most persistent changes in brain function that may occur in adult life. The neural substrates of memory are likely to include alterations in synaptic weights, such as long-term potentiation or long-term depression, and physical remodeling of dendritic spines.

Cues that can reinitiate drug use include environmental stimuli (e.g., persons with whom drugs have been used, drug paraphernalia) and body feelings. Because addictive drugs reliably increase synaptic dopamine and other reward-related neurotransmitters as a result of their direct pharmacologic actions—indeed, they produce excessive and grossly distorted reward signals—the brain receives a powerful impetus to connect the circumstances in which the drugs have been used with the motivation to take drugs again. Addictive drugs also activate transcription factors, such as the cyclic adenosine monophosphate response element binding protein, and alter the composition of activator protein 1 complexes in brain reward circuits.[19] Cocaine, opioids, and other addictive drugs regulate many genes downstream of these and other transcription factors. Even if the drug is no longer pleasurable, these signals continue to reinforce drug wanting and seeking. Moreover, the certainty and magnitude of these signals give drugs a marked advantage over natural rewards and other learned goals, including prosocial activities.

28 IMMUNOMODULATORY DRUGS

ANNE R. BASS AND INEZ ROGATSKY

Even with the availability of targeted biologic treatments (Chapter 29), synthetic immunomodulatory drugs remain the cornerstone of therapy for many autoimmune conditions, including rheumatoid arthritis, juvenile inflammatory arthritis, psoriatic arthritis, and systemic lupus erythematosus (Table 28-1). When used for rheumatic diseases, these agents are often referred to as disease-modifying antirheumatic drugs (DMARDs). Orally bioavailable and relatively inexpensive, these agents target intracellular processes important for the survival and/or function of immune cells. Many, although not all, of these agents are immunosuppressive; that is, they predispose patients to infection. With the exception of glucocorticoids, synthetic immunomodulatory agents are slow acting, generally taking 2 to 3 months to have their therapeutic effect. Some synthetic immunomodulatory drugs are U.S. Food and Drug Administration (FDA)–approved for a narrow group of conditions but are used more widely in clinical practice. For example, mycophenolate mofetil is FDA-approved for the prevention of transplant rejection but is often used to treat systemic lupus erythematosus.

GLUCOCORTICOIDS

First introduced into clinical practice in the early 1950s, glucocorticoids remain among the most commonly prescribed class of medications worldwide, primarily due to their extremely potent immunosuppressive and anti-inflammatory properties and very low cost. Despite their efficacy, serious side effects associated with glucocorticoid use prompted the race for "selective," less toxic, glucocorticoid-like compounds; however, no such new-generation glucocorticoids have yet become available. A fundamental difference setting glucocorticoids apart from other anti-inflammatory medications is that they are modeled after endogenously produced steroid hormones with numerous functions in normal mammalian physiology. Hence, "adverse effects" of their administration are not "off-target" but rather reflect expected responses of biologic systems receiving these hormones in excess of their physiologic levels and irrespective of the normal circadian cycle of glucocorticoid secretion. Endogenous glucocorticoids are produced from cholesterol by the adrenal cortex along with structurally similar mineralocorticoids (the unifying term *corticosteroids* refers to both types of molecules). These hormones signal through the glucocorticoid and mineralocorticoid receptors, respectively; however, the main endogenous glucocorticoid, cortisol, can bind both receptors. Most synthetic clinically used glucocorticoids have much higher affinity for the glucocorticoid receptors.[1]

GLUCOCORTICOID RECEPTOR

The human glucocorticoid receptor gene (*NR3C1*) encodes the main 795–amino acid GRα protein that is responsible for the majority of glucocorticoid activities and a GRβ splice variant that differs from GRα in its unique C-terminus beyond amino acid 728 and does not bind hormone. The physiologic significance of the β-isoform has been debated and likely differs between cell types depending on how much β-isoform is expressed; it has been reported to function as a dominant-negative inhibitor of GRα in certain contexts. In addition, the alternate translation start sites of GRα may give rise to different isoform combinations present in different tissues. GRα protein is a member of the nuclear receptor family—the largest family of mammalian transcription factors. Upon activation by its endogenous or synthetic hormonal ligand, cytoplasmic heat-shock protein-bound GRα undergoes structural changes and translocates to the cell nucleus, where it either binds DNA directly—typically, a specific palindromic sequence known as a glucocorticoid response element—or is tethered to DNA through protein:protein interactions with other DNA-bound regulators, particularly those of the activator protein-1 (AP1) and nuclear factor-κB (NF-κB) families (Fig. 28-1). In each case, GRα can activate or repress transcription. Commonly, however, GRα binding to palindromic glucocorticoid response elements leads to activation of associated genes, whereas binding to AP1/NF-κB represses transcription of their target genes (Fig. 28-1). Anti-inflammatory and immunosuppressive properties of glucocorticoids result both from direct activation of anti-inflammatory (interleukin [IL]-10, dual specificity phosphatase-1 [Dusp1], glucocorticoid-inducible leucine-zipper [Gilz], TNFAIP3/A20, and others) and repression of AP1- and/or NF-κB–driven pro-inflammatory genes.

The extremely broad consequences of glucocorticoid actions stem from the fact that the GRα protein is expressed essentially in every cell in the body. In each cell type, the glucocorticoid receptor activates and represses hundreds of genes, thereby leading to specific physiologic effects. Recent genome-wide analyses of GRα binding and glucocorticoid-regulated transcriptomes revealed a striking level of specificity in the glucocorticoid receptor's actions, whereby even in closely related cell types (e.g., different types of white blood cells), glucocorticoid receptor–regulated genes display a mere 15% overlap. This finding indicates that cell-specific variables (e.g., chromatin packaging and accessibility to transcription factor binding), the composition of GRα interacting accessory proteins (e.g., coactivators and corepressors that associate with GRα in a cell- and binding site–specific manner), and the physiologic state of the cell play major roles in specifying glucocorticoid function (Fig. 28-1).

TABLE 28-1 RECOMMENDED GLUCOCORTICOID DOSE TAPERING SCHEDULES, SUBJECT TO INDIVIDUAL VARIABILITY AND REQUIRING MONITORING OF PATIENT'S CLINICAL RESPONSE*

STARTING DOSE OF PREDNISONE (OR EQUIVALENT)	PROGRESSIVE DECREASE OF DAILY DOSE
>40 mg daily	5-10 mg daily every 1-2 weeks
20-40 mg daily	5 mg daily every 1-2 weeks
10-19 mg daily	2.5 mg daily every 2-3 weeks
5-9 mg daily	1 mg daily every 2-4 weeks
<5 mg daily	0.5 mg daily every 2-4 weeks

*Recommended schedules can be modified for individual patients, depending on the disease and the duration of glucocorticoid treatment.

PHYSIOLOGIC AND PHARMACOLOGIC EFFECTS OF GLUCOCORTICOIDS IN DIFFERENT TISSUES

Glucocorticoids and Inflammation

One of the most well-known effects underlying the widespread use of glucocorticoids is suppression of inflammation. This effect stems from dramatic reduction

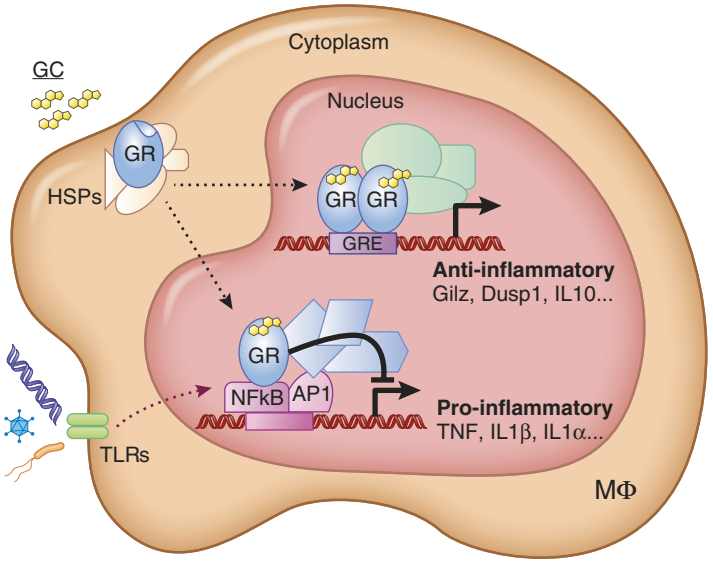

FIGURE 28-1. Glucocorticoid receptor (GR) signaling pathway. Unliganded GR is cytoplasmic and bound by heat-shock proteins (HSPs) that maintain its competence for glucocorticoid (GC) ligand binding. When GC-bound, GR undergoes structural change, translocates to the nucleus, and associates with specific genomic glucocorticoid response elements (GREs) (two hexameric head-to-tail [inverted] half-sites separated by three base pairs) or tethers to DNA through protein:protein interactions with AP1 and NF-κB, the effector pro-inflammatory transcription factors downstream of toll-like receptors (TLRs). In each case, a number of coactivator and corepressor proteins associate with GR in a binding site–specific manner. Some proteins encoded by genes activated and repressed by GR in a macrophage (MΦ) through direct DNA binding and tethering, respectively, are listed. AP1 = activator protein 1; IL = interleukin; NFκB = nuclear factor kappa light chain enhancer of activated B cells; TNF = tumor necrosis factor.

ABSTRACT

Synthetic immunomodulatory drugs are oral agents that target intracellular processes important for the survival and/or function of immune cells. Glucocorticoids are the most widely used (and least expensive) of these agents. Glucocorticoids bind to glucocorticoid receptors that are expressed not only on inflammatory cells but also on cells of the cardiovascular system, bone, muscle, liver, adipose tissue, and central nervous system. As a consequence, they have both profound immunosuppressive and anti-inflammatory effects but can also result in significant toxicity. Methotrexate, leflunomide, and mycophenolate mofetil are immunosuppressive drugs commonly used to treat rheumatic diseases, while the immunophilin-binding agents, cyclosporine, tacrolimus, and sirolimus, are most commonly used to prevent transplant rejection.

rheumatic disease

in the transcription of genes encoding inflammatory cytokines (tumor necrosis factor [TNF], IL-1α, IL-1β, IL-12p40, IL-6), chemokines (Cxcl10, Ccl2, Ccl3, Ccl4, Ccl5), and cell adhesion molecules (ICAM, ELAM), along with other mediators of inflammation (such as those produced through the activity of cyclooxygenase-2 and phospholipase A2: prostaglandins, leukotrienes, and arachidonic acid metabolites) produced by macrophages, endothelial cells, fibroblasts, and other cell types. These changes yield a less inflammatory environment, reducing leukocyte and lymphocyte trafficking, as well as their numbers, due to both a decrease in proliferation and an increase in apoptosis for certain cell subsets. It should be noted that glucocorticoid receptor–mediated apoptosis, specifically of immature and transformed lymphocytes, makes glucocorticoids the drug of choice for numerous hematologic malignancies.

Physiologically, glucocorticoid production in inflammatory conditions is triggered through the activation of the hypothalamic-pituitary-adrenal (HPA) axis by inflammatory cytokine signaling when the local mechanisms to control inflammation fail. This effect is transient and self-limited due to a negative feedback loop back to the hypothalamus that suppresses excessive HPA activity.[2] Pharmacologically, prolonged or high-dose glucocorticoid administration is not susceptible to HPA-mediated inhibition and may lead to immunosuppression and increased susceptibility to infections. It is important to note that the effect of glucocorticoids on immune cell types is not indiscriminately suppressive but modulatory and generally favors Th2-type T-cell responses while suppressing Th1; similarly, glucocorticoids inhibit the function of inflammatory macrophages while promoting macrophage commitment to the homeostatic anti-inflammatory phenotype.

Glucocorticoids and Metabolism in the Liver, Adipose Tissue, and Muscle

As the name suggests, endogenous glucocorticoids are critical mediators of glucose, as well as lipid and protein metabolism. In the liver, glucocorticoids are essential for maintaining normal blood glucose levels during fasting, awakening, and periods of stress, partly by increasing the hepatic responsiveness to glucagon. This occurs through stimulation of gluconeogenesis (indeed, GR activates genes encoding rate-limiting enzymes of gluconeogenesis such as *PEPCK*). Glucocorticoids have also been implicated in the regulation of fatty acid metabolism in the liver. In the adipose tissue, glucocorticoids both increase adipocyte differentiation and decrease lipolysis upon chronic exposure; the result is to promote visceral fat accumulation. Finally, in the skeletal muscle, glucocorticoids inhibit protein synthesis while promoting proteolysis to provide amino acids for gluconeogenesis.

The compound systemic effects of glucocorticoid excess on the key metabolic tissues—the liver, adipose tissue, and muscle—are perhaps best highlighted in patients with Cushing syndrome (Chapter 208) resulting from pituitary or adrenocortical adenomas or long-term administration of glucocorticoid medications. These include glucose intolerance due to increased gluconeogenesis in the liver and antagonism of the effects of insulin on peripheral glucose utilization, fasting and postprandial hyperglycemia, and reduced insulin sensitivity[3]—typical signs of type 2 diabetes and metabolic syndrome (Chapter 210). Patients with Cushing syndrome often present with dyslipidemia due to both an increase in triglyceride and total cholesterol levels and adipocyte differentiation in the visceral adipose tissue, ultimately leading to centripetal adiposity. Finally, catabolic effects of high circulating glucocorticoids in the muscle result in skeletal muscle atrophy and weakness.

Glucocorticoids and the Cardiovascular System

Glucocorticoids are required to maintain blood volume and pressure, as well as normal arteriolar tone and cardiac output. Consequently, sustained exposure to high-dose glucocorticoids results in elevated blood pressure—an effect observed both in patients with Cushing syndrome and in individuals treated with glucocorticoids. Of note, in Cushing syndrome, a part of this effect is a consequence of increased retention of water and sodium by the kidneys—an activity of mineralocorticoid receptors, rather than glucocorticoid receptors, activated by endogenous cortisol. However, synthetic glucocorticoids lacking any mineralocorticoid receptor–binding activity have an independent glucocorticoid receptor–mediated effect on blood pressure by suppressing the production of vasodilators (e.g., prostaglandins and endothelial nitric oxide) while stimulating the responsiveness to vasoconstrictors (e.g., vasopressin and catecholamines) and augmenting the expression of angiotensin II receptors, ultimately increasing peripheral vascular resistance (Chapter 64).

Glucocorticoids and the Bones

Two of the most debilitating adverse effects of glucocorticoid treatment are osteoporosis (Chapter 225)[4] and osteonecrosis (Chapter 229). Glucocorticoids have a spectrum of functions in normal bone physiology by acting upon both key cell types: osteoblasts and osteoclasts (Chapter 225). Glucocorticoids are required for normal bone growth and remodeling; they stimulate osteoclastogenesis, in part, by activating the expression of RANK ligand—a critical growth factor for osteoclast maturation—while inhibiting the expression of its decoy receptor osteoprotegerin in surrounding osteoblasts and stromal cells, ultimately leading to bone resorption. At the same time, glucocorticoids inhibit osteoblast proliferation and differentiation (by shifting stromal cell differentiation from osteoblasts to adipocytes) and promote their apoptosis. Clinically, these activities may result in significant bone loss and an increased risk of fractures, especially with prolonged use (>3 months) of oral corticosteroids or high cumulative doses of potent topical corticosteroids.[5] Fortunately, however, these effects can be lessened by co-administration of bisphosphonates, denosumab (a RANK ligand inhibitor at 60 mg subcutaneously every 6 months), or teriparatide (a recombinant parathyroid hormone at 20 μg subcutaneously daily).[A1]

Glucocorticoids and the Central Nervous System

At normal levels, glucocorticoids have long been known to be critical in the hippocampus, where they facilitate memory and learning. There is also extensive evidence that excessive glucocorticoids (including endogenous glucocorticoids during a sustained period of stress) are associated with decreased hippocampal cellularity, impaired memory, and changes in mood, cognition, and reasoning. Similarly, although adequate levels of glucocorticoids are protective against acute traumatic stress, repeated high-dose glucocorticoid treatment mimics chronic stress and induces dendritic lengthening in the basolateral amygdala—a region responsible for developing fear, anxiety, and aggression. Notably, experimental evidence also shows that exposure of the brain to increased amounts of glucocorticoids early in life or even in utero may have long-lasting consequences for the HPA axis and glucocorticoid-regulated processes such as metabolism and cardiovascular function.

Overall, while physiologic, diurnal, or acute stress-induced secretion of glucocorticoids is essential for normal brain functions and protection from stress-induced damage, sustained elevated levels of glucocorticoids cause a spectrum of central nervous system pathologies whose severity depends on the dose, duration, and time of exposure, as well as genetic, epigenomic, and environmental factors at play.

Clinical Use

Glucocorticoids are approved for use in a wide variety of inflammatory conditions at a range of doses and durations. Glucocorticoids can be used for short-term management of disease flares, such as in patients with asthma, gout, rheumatoid arthritis, juvenile inflammatory arthritis, or psoriatic arthritis, and for patients experiencing acute allergic reactions. A short course of corticosteroids also improves outcomes in ventilated patients with coronavirus 2019 diseases (Chapter 337). Other conditions require sustained glucocorticoid use to maintain disease remission, such as sarcoidosis, ulcerative colitis, eczema, minimal change glomerulonephritis, systemic lupus erythematosus, dermatomyositis, temporal arteritis, and polymyalgia rheumatica. Low doses (≤10 mg) are often adequate for rheumatoid arthritis and polymyalgia rheumatica, whereas high doses (e.g., prednisone 1 mg/kg) are required for the acute management of giant cell arteritis, lupus nephritis, and dermatomyositis. Inhaled glucocorticoids can be used for the management of asthma and chronic obstructive pulmonary disease, whereas intra-articular glucocorticoids are used to control localized joint symptoms in patients with inflammatory arthritis and osteoarthritis. Repeated intra-articular glucocorticoid injections can be associated with more rapid cartilage loss in osteoarthritis patients, however. Finally, glucocorticoids can be administered topically for the treatment of psoriasis, eczema, and other skin conditions.

Management of glucocorticoids in the perioperative period for patients on chronic steroid therapy has been traditionally based on an assumption that supraphysiologic dose increases are always required to avoid the development of adrenal insufficiency. Based on the negative results of a small number of randomized trials to test this assumption and more recent clinical experience, along with the risks of hypertension, fluid retention, hyperglycemia, and infection with the routine use of high-dose glucocorticoid supplementation, this practice should be reserved for special situations. With (1) major surgical procedures, (2) the presence of volume-refractory hypotension, or (3) in patients requiring chronic physiologic replacement therapy for adrenal insufficiency, it has been recommended that patients should receive their steroid dose right up to the time of surgery, followed by hydrocortisone 50 to 100 mg intravenously started prior to surgery, followed by a 200-mg continuous infusion

over 24 hours or by 50 to 100 mg repeated every 8 hours for at most 48 to 72 hours postoperatively (based on the known normal secretory rate of cortisol of 75 to 150 mg daily during anesthesia and major surgery).[6] Either of these regimens should be immediately followed by replacement with the patient's oral glucocorticoid therapy. Conversely, perioperative supplemental glucocorticoids are not indicated for minor or intermediate-intensity surgical procedures, for patients who are chronically taking prednisone (or equivalent) at doses of 10 mg or less daily, for patients who are on every-other-day steroids, or for patients who are using only topically administered steroids. In all these cases, treating physicians should be promptly reactive, with exogenous glucocorticoids administered in case of unexpected postoperative hypotension or other manifestations of adrenocortical insufficiency. The recommendations for withholding supraphysiologic steroid therapy perioperatively in the settings described earlier do not apply to individuals taking chronic glucocorticoid replacement for adrenal failure or to generally any surgery in children chronically treated with glucocorticoids.

Toxicity and Monitoring

Glucocorticoid toxicity is dose and duration dependent. Even inhaled glucocorticoids for asthma (Chapter 75) have metabolomic side effects,[7] and just a short burst of high-dose oral glucocorticoid therapy increases the short-term risk of gastrointestinal bleeding, heart failure, and sepsis by about three-fold.[8] Common toxicities include weight gain, Cushing syndrome, osteoporosis, osteonecrosis, diabetes, hypertension, hyperlipidemia, posterior subcapsular cataracts, increased intraocular pressure, skin fragility, poor wound healing, gastrointestinal tract bleeding and perforation, mood changes, myopathy, and predisposition to infection, including opportunistic ones. Glucocorticoids administered to children can also result in growth retardation. Patients starting glucocorticoids should be counseled to take supplemental calcium and vitamin D; additional treatments to prevent osteoporosis depend on the anticipated dose and duration of glucocorticoid treatment, the patient's age, and baseline osteoporosis risk.

Because patients on exogenous glucocorticoids can develop secondary adrenal insufficiency, the dose of glucocorticoids should be tapered gradually to accommodate a slow return of adrenal function (Table 28-1). Different tapering regimens for glucocorticoids in different diseases are based on a very low quality of evidence. Considering the sizable individual variation in response to tapering, it is unlikely that a secure, uniform glucocorticoid tapering schedule applicable to all patients will be determined in the foreseeable future, as recently summarized. A systematic, broadly based review estimated the risk of clinical or subclinical adrenal insufficiency after glucocorticoid withdrawal to be approximately 30% after use of a variety of types of glucocorticoids in several underlying diseases. The problem of this apparently high rate of adrenal insufficiency is compounded by its difficulty in recognition, because symptoms and signs are usually nonspecific (e.g., nausea, vomiting, abdominal cramps, fatigue) and insidious in onset. Dosage, duration of treatment, administration route, age, fragility, underlying disease, and even laboratory testing of serum cortisol level are not completely useful in predicting adrenal insufficiency. Some generalizations can be made regarding glucocorticoid withdrawal[9]:

1. Hypothalamic-pituitary-adrenal (HPA) axis suppression mostly occurs after oral or parenteral glucocorticoid treatment that leads to higher systemic levels of glucocorticoids, but it may also appear with cutaneous, ototopical, or ophthalmic administration.
2. HPA suppression is improbable in patients who have received glucocorticoid treatment for less than 3 weeks.
3. HPA suppression is improbable in patients who have received daily prednisone at a dose of less than 5 mg (or equivalent) or alternate-day prednisone at doses of less than 10 mg (or equivalent).
4. Repeated biochemical monitoring for adrenal insufficiency with glucocorticoid withdrawal is impractical. If needed, a first assessment that measures morning serum cortisol level (between 8:00 and 9:00 AM) may be helpful but not conclusive in most cases. Among classical stimulatory tests to diagnose adrenal insufficiency, the insulin tolerance test is considered the gold standard, but it requires medical supervision because of its risk and is contraindicated in several populations. A standard-dose corticotropin analog test may be more reliable and accurate than the morning cortisol level, but it is cumbersome.
5. Patients who have adrenal insufficiency upon glucocorticoid withdrawal usually respond symptomatically to reinstitution of glucocorticoid therapy.
6. During the year after discontinuing glucocorticoids, patients should be well educated on the risks of adrenal insufficiency[10] and know that they may require glucocorticoids in situations of stress (such as surgery or significant medical illness) to compensate for reduced adrenal glucocorticoid production.

Notwithstanding the complex variables that determine the effectiveness and safety of glucocorticoid tapering, which may also include genetic determinants, an example of a general tapering scheme might be a stable reduction of 10 to 20% with monitoring of clinical response of the patient (see Table 28-1).

Glucocorticoid use in pregnancy can be associated with low-birthweight babies and may slightly increase the risk of cleft palate, but glucocorticoids are commonly used in pregnancy when needed by the mother (Chapter 221). Prednisone and prednisolone are metabolized to an inactive form by placental 11β-hydroxysteroid dehydrogenase and do not reach the fetus. In contrast, fluorinated glucocorticoids such as dexamethasone and betamethasone do cross the placenta and are used predelivery to treat the fetus and induce fetal lung maturation.

IMMUNOMODULATORY AGENTS

Hydroxychloroquine

Mechanism of Action

The mechanism of action of hydroxychloroquine is not fully understood, but the drug is known to reduce lysosomal activity and autophagy (the process in which organelles and proteins are sequestered into vesicles that fuse with lysosomes to be broken down and used as fuel for other cellular needs). Hydroxychloroquine also reduces the presentation of class II major histocompatibility complex autoantigens, as well as signaling through toll-like receptors 7 and 9. Hydroxychloroquine is given as a once- or twice-daily oral dose; it is readily absorbed and has a long half-life due to extensive tissue uptake.

Clinical Use

Hydroxychloroquine was developed to treat malaria but is also approved for the treatment of systemic lupus erythematosus (Chapter 245) and rheumatoid arthritis (Chapter 243). Hydroxychloroquine can help to control lupus skin disease, arthritis, serositis, and mild hematologic abnormalities, and discontinuing hydroxychloroquine increases the risk of a lupus flare. Hydroxychloroquine is not used as primary treatment for lupus nephritis, but the drug can help reduce the risk of end-stage renal disease in these patients. Hydroxychloroquine also reduces the risk of type 2 diabetes and venous thromboembolism, lowers cholesterol levels, and improves overall lupus survival. In patients with rheumatoid arthritis, hydroxychloroquine is a component of "triple therapy" (along with sulfasalazine and methotrexate), which is as effective as methotrexate plus a TNF inhibitor. Hydroxychloroquine is also used in some inflammatory and rheumatic skin diseases, mainly as a steroid-sparing agent.

Toxicity and Monitoring

Hydroxychloroquine can cause retinopathy, which is treatment dose and duration related. Retinopathy risk can be minimized by using a dose less than or equal to 5 mg/kg and by referring the patient for ophthalmologic screening. Hydroxychloroquine can also be associated with pruritus, areas of blue-gray "bruiselike" skin pigmentation, particularly on the lower extremities, cardiomyopathy, prolongation of the QT interval, proximal myopathy, and peripheral neuropathy. Hydroxychloroquine is not associated with fetal malformations and is generally continued during pregnancy in lupus patients in order to prevent a disease flare.

Sulfasalazine

Mechanism of Action

Sulfasalazine is metabolized by intestinal bacteria to sulfapyridine and 5-aminosalicylic acid (5-ASA). Sulfapyridine is well absorbed, whereas most of the 5-ASA remains in the intestine. 5-ASA appears to be responsible for the therapeutic effect of sulfasalazine in ulcerative colitis (Chapter 127) through an unknown mechanism. It should be noted that 5-ASA is a weak cyclooxygenase 1 and 2 inhibitor, and traditional nonsteroidal anti-inflammatory agents, which strongly inhibit cyclooxygenase, actually worsen colitis. How sulfasalazine ameliorates rheumatoid arthritis is unknown. Sulfasalazine is given in split daily doses ranging from 2 to 4 g/day.

Clinical Use

Sulfasalazine is approved for the treatment of ulcerative colitis (Chapter 127), as well as polyarticular juvenile inflammatory arthritis and rheumatoid arthritis. In rheumatoid arthritis, sulfasalazine is a component of "triple therapy" (along with hydroxychloroquine and methotrexate), which has been shown

to be as effective as methotrexate plus a TNF inhibitor. Sulfasalazine is also used in the treatment of psoriatic arthritis.

Toxicity and Monitoring

Sulfasalazine can be associated with severe hypersensitivity reactions and should never be given to individuals with sulfa or aspirin allergy. Sulfasalazine can also cause agranulocytosis (Chapter 153) and aplastic anemia (Chapter 151). More common side effects of sulfasalazine include gastrointestinal upset, headache, and liver dysfunction.

Sulfasalazine has not been associated with fetal abnormalities; however, because sulfasalazine can inhibit folate absorption, folic acid supplementation is especially important in pregnant women taking the drug. Sulfasalazine can cause reversible oligospermia, and alternative treatments should be considered in male patients attempting to conceive a child.

IMMUNOSUPPRESSIVE AGENTS

Methotrexate

Mechanism of Action

Methotrexate inhibits dihydrofolic acid reductase, which results in antiproliferative effects via reduced synthesis of purines, pyrimidines, and polyamines. Methotrexate polyglutamates (metabolites) also inhibit aminoimidazole carboxamide ribonucleotide transformylase, an inhibitor of adenosine deaminase. This results in high intracellular levels of adenosine, which, when released, can have anti-inflammatory effects on neutrophils, macrophages, and lymphocytes. Oral absorption of methotrexate is dose dependent and varies among individuals. Subcutaneous dosing can be used to ensure bioavailability and helps to reduce gastrointestinal side effects. Methotrexate is excreted largely through glomerular filtration and active tubular secretion, and dose reduction is important in individuals with renal insufficiency, such as the elderly. Methotrexate is administered weekly as either a single dose or in three divided doses 12 hours apart over a 24-hour period. Although high-dose methotrexate (20 to 25 mg per week) is associated with greater efficacy than lower doses (5 to 15 mg per week), dosages are generally "ramped up" while monitoring for dose-dependent toxicities.

Clinical Use

Along with cyclosporine and acitretin, methotrexate is approved as one of the conventional systemic immunomodulatory treatments of psoriasis (Chapter 405). Several biologic agents have since emerged for the treatment of moderate to severe psoriasis. Methotrexate is FDA-approved for the treatment of rheumatoid arthritis,[11] polyarticular juvenile inflammatory arthritis, and psoriatic arthritis. Methotrexate monotherapy is recommended as the first-line treatment in patients with early rheumatoid arthritis, with or without glucocorticoid therapy (Chapter 243). If disease activity remains high, then methotrexate can be combined with hydroxychloroquine and/or sulfasalazine or combined with a biologic DMARD, generally a TNF inhibitor or a Janus kinase inhibitor. In patients with psoriatic arthritis (Chapter 244), methotrexate is effective in treating peripheral arthritis and psoriasis but is not effective in treating enthesitis, dactylitis, or nail or spine involvement.

Toxicity and Monitoring

In addition to predisposing patients to infection, methotrexate can cause liver toxicity and bone marrow suppression.[12] Complete blood counts and liver function testing should be performed monthly for 3 months at the initiation of therapy (and after changes in dose) and every 3 to 4 months thereafter. Renal function should also be monitored because a fall in glomerular filtration rate reduces methotrexate clearance. Alcohol should be avoided in patients on methotrexate, and methotrexate should not be prescribed to individuals with underlying liver disease. Patients with psoriasis (Chapter 405), particularly patients who have diabetes or who are obese, appear to be at higher risk of liver toxicity than patients with rheumatoid arthritis. Liver biopsy may be recommended in psoriatic patients who have received a cumulative methotrexate dose between 1.5 and 4 grams, depending on their level of risk. Non-Hodgkin lymphoma (Chapter 171) has been reported in patients treated with methotrexate, including some cases that regressed without additional treatment upon withdrawal of methotrexate. Methotrexate can be associated with acute pneumonitis or pulmonary fibrosis, and smokers are at increased risk for pulmonary toxicity. In patients with rheumatoid arthritis, methotrexate-induced lung injury can sometimes be difficult to distinguish from rheumatoid lung disease. Stomatitis, nausea, malaise, and fatigue are other relatively common side effects of methotrexate. Toxicity can be lessened by administration of folic acid 1 mg daily or folinic acid 5 mg weekly 12 to 24 hours after each methotrexate dose.

Methotrexate is teratogenic and can also cause fetal death. It is contraindicated in pregnant women and nursing mothers, and it should not be used for at least 3 months before planned conception in either men or women.

PURINE AND PYRIMIDINE INHIBITORS

Leflunomide

Mechanism of Action

Leflunomide inhibits dihydro-orotate dehydrogenase and thereby results in decreased pyrimidine synthesis and antiproliferative effects. Leflunomide is given as a daily 20-mg dose. It has a long half-life (≈2 weeks) due to biliary recycling, and using a loading dose (100 mg daily × 3 days) at treatment initiation leads to a more rapid clinical response. Leflunomide has both renal (early) and fecal (late) elimination, and in cases of severe leflunomide toxicity, a cholestyramine washout (cholestyramine 8 g three times daily × 11 days) causes rapid drug elimination. Without a washout, leflunomide metabolites remain detectable in the blood for up to 2 years.

Clinical Use

Leflunomide is FDA-approved for the treatment of rheumatoid arthritis (Chapter 243), where it improves signs and symptoms of the disease and prevents structural damage. Leflunomide is also used in the management of peripheral arthritis in patients with psoriatic arthritis.

Toxicity and Monitoring

Leflunomide can cause severe liver injury, including fatal liver failure. Leflunomide can also cause marrow suppression and predispose patients to infection. Liver function testing and complete blood counts should be performed monthly for 3 to 6 months at the initiation of therapy and every 2 to 3 months thereafter. If there is a three-fold rise in aminotransferase levels, then leflunomide should be discontinued and a cholestyramine washout used. As with methotrexate, there are reports of leflunomide-associated interstitial lung disease. Leflunomide commonly causes diarrhea and mild alopecia. Minor side effects may resolve with leflunomide dose reduction. Although there are no data specifically linking leflunomide to the development of malignancy, the risk of lymphoma may be increased in any patient on immunosuppressive therapy.

Leflunomide is teratogenic and can also cause fetal death; it is contraindicated in pregnant women and nursing mothers, and it should not be used in women of childbearing age who are not using contraception. Women planning pregnancy should stop leflunomide and use a cholestyramine washout. Pregnancy should not be attempted until the blood leflunomide M1 metabolite level is less than 0.02 mg/L on two separate tests at least 2 weeks apart.

Mycophenolate Mofetil

Mechanism of Action

Mycophenolate mofetil is rapidly metabolized to mycophenolic acid, the active metabolite.[13] Mycophenolic acid blocks the function of inosine monophosphate dehydrogenase and thereby inhibits the de novo pathway of guanosine synthesis. Because T and B lymphocytes lack salvage pathways to synthesize purines, mycophenolate mofetil acts preferentially on lymphocytes. In addition to these antiproliferative effects, mycophenolate mofetil reduces antibody formation by B cells. Mycophenolate mofetil is given orally twice daily, with dose reduction in patients with severe renal impairment.

Clinical Use

Mycophenolate mofetil is approved for use in kidney, liver, and heart transplant (Chapter 38) recipients in combination with cyclosporine and glucocorticoids. Mycophenolate mofetil has also been shown to be as effective as cyclophosphamide in inducing remission of lupus nephritis and superior to azathioprine in maintaining remission of lupus nephritis (Chapter 245). Mycophenolate mofetil is as effective as cyclophosphamide in the management of scleroderma-related interstitial lung disease.

Toxicity and Monitoring

Mycophenolate mofetil can cause neutropenia and other cytopenias. Nausea and diarrhea are common with the drug. Mycophenolate mofetil increases the risk of infection and may also increase the risk of lymphoma.

Mycophenolate mofetil is a pregnancy category D drug that has been associated with congenital malformations and miscarriages and is contraindicated in pregnancy. Reliable contraception should be used in women of childbearing

age on mycophenolate mofetil, and contraception should be continued for at least 6 weeks after discontinuing the drug. Breast-feeding should also be avoided in mothers on mycophenolate mofetil.

Azathioprine and 6-Mercaptopurine

Mechanism of Action

Azathioprine is a derivative of 6-mercaptopurine (6-MP), and their effects are similar. Both drugs are activated by hypoxanthine-guanine phosphoribosyltransferase (HGPRT) to form 6-thioguanine nucleotides that can be incorporated into DNA, causing cytotoxicity. Other drug metabolites inhibit the enzyme glutamine-5-phosphoribosylpyrophosphate amidotransferase, required for de novo purine synthesis. Both drugs result in dose-dependent suppression of delayed-type hypersensitivity and cytotoxicity. Azathioprine and 6-MP are metabolized in the liver and in erythrocytes via two pathways, one using thiopurine S-methyltransferase (TPMT) and the other using xanthine oxidase. Ten percent of the population is heterozygous for a nonfunctioning TPMT allele and 0.3% are homozygous for this allele, resulting in intermediate or low to absent TPMT levels, respectively. Patients with low or absent TPMT can experience life-threatening myelosuppression when given azathioprine or 6-MP, while those with intermediate levels benefit from lower drug dosages. TPMT testing (level or genotype) can help identify individuals at increased risk of myelotoxicity, but because myelotoxicity can occur even in the presence of normal TPMT levels, all patients require close monitoring of complete blood counts, particularly at the initiation of therapy and with any dose change. The second route of azathioprine and 6-MP inactivation, via xanthine oxidase, can be inhibited by xanthine oxidase inhibitors, such as allopurinol or febuxostat, used in the treatment of gout. The dose of azathioprine or 6-MP must be reduced when one of these drugs is used. Azathioprine and 6-MP are given as a single or split daily dose. The daily dose of azathioprine in patients with autoimmune diseases and as maintenance to prevent transplant rejection is 1 to 3 mg/kg.

Clinical Use

Azathioprine is approved for the treatment of rheumatoid arthritis, though rarely used for this indication, and as adjunctive therapy in the prevention of renal transplant rejection (Chapter 117). 6-MP is approved for the treatment of acute lymphatic leukemia as part of a combination regimen. Azathioprine and 6-MP can help to maintain remission in ulcerative colitis[14] and are sometimes used as steroid-sparing agents in Crohn disease (Chapter 127). Azathioprine is most commonly used as a steroid-sparing agent in systemic lupus erythematosus (Chapter 245).

Toxicity and Monitoring

Bone marrow suppression is common and dose-related in patients receiving azathioprine or 6-MP, and it can result in leukopenia, anemia, and thrombocytopenia. Gastrointestinal side effects, including nausea, vomiting, diarrhea, and elevated liver enzymes, are common, and azathioprine can also cause pancreatitis. Complete blood counts and measurement of liver enzymes should be performed every 1 to 2 weeks during the first month of treatment and with every change in dose, every 2 weeks for an additional 2 months, and then every 3 months thereafter. Azathioprine and 6-MP are associated with an increased risk of infections, lymphoma, and skin cancer. Rare cases of hepatosplenic T-cell lymphoma have been reported in inflammatory bowel disease patients receiving azathioprine.

Azathioprine and 6-MP are categorized as pregnancy category D drugs because they can be associated with prematurity, low birthweight, neonatal leukopenia, thymic hypoplasia, and hypogammaglobulinemia. However, immunologic effects on the fetus generally normalize within 1 year, and azathioprine is not associated with fetal malformations. For this reason, azathioprine is often continued in pregnant lupus patients, especially if they have a recent history of nephritis.

IMMUNOPHILIN-BINDING AGENTS, INCLUDING CALCINEURIN INHIBITORS

Cyclosporine

Mechanism of Action

Cyclosporine binds to cyclophilin A, the predominant immunophilin in T cells, and this binding enhances cyclophilin's inhibition of calcineurin. Calcineurin is stimulated during T-cell activation to activate nuclear factor of activated T cells (NFAT), which in turn leads to the production of IL-2 and other cytokines important in the immune response. Calcineurin also indirectly enhances activation of NFκB, which is critical for T-cell function and survival. Cyclosporine also has calcineurin-independent inhibitory effects on the mitogen-activated protein kinase (MAPK) pathway. Cyclosporine is metabolized by cytochrome P-450 3A (CYP3A) in the liver, and 95% of excretion is biliary. Drug clearance is also strongly stimulated by P-glycoprotein expression on intestinal enterocytes. Cyclosporine is given twice daily as a divided oral dose. Daily dosages for patients with rheumatic diseases are lower than maintenance doses used to prevent transplant rejection (2 to 4 mg/kg vs. 7 to 9 mg/kg, respectively). Trough drug levels should be measured to determine the optimal therapeutic dose, especially in transplant patients. Therapeutic drug concentrations differ with the measurement technique, institution, indication, and protocol. Drug interactions occur when cyclosporine is co-administered with inhibitors or inducers of CYP3A or P-glycoprotein. Azole antifungal agents, macrolide antibiotics, and calcium-channel blockers increase cyclosporine levels, whereas many anticonvulsants and St. John's wort decrease cyclosporine levels.

Clinical Use

Cyclosporine is FDA-approved for the treatment of severe plaque psoriasis (Chapter 405) and to prevent allogeneic kidney, heart, and liver transplant rejection (Chapter 38). It is also approved for the treatment of active rheumatoid arthritis but is not commonly used for this indication. In patients with psoriasis, cyclosporine is generally used intermittently and for less than 12 weeks to avoid cumulative toxicity. Cyclosporine is also a first-line treatment for pure red cell aplasia (Chapter 151). Voclosporin, a cyclosporine analogue, is approved for the treatment of active lupus nephritis in patients who are on background therapy with mycophenolate mofetil.

Toxicity and Monitoring

Cyclosporine can cause hypertension, renal insufficiency, hyperkalemia, and hyperuricemia. In patients with rheumatoid arthritis and psoriasis, blood pressure and creatinine levels should be monitored every 2 weeks during initiation of treatment and every 1 to 3 months during long-term use. If the creatinine level rises 25% above baseline, then testing should be repeated and the dosage reduced 25 to 50% if there is no improvement. Nonsteroidal anti-inflammatory drugs (NSAIDs) should be avoided in patients taking cyclosporine. Psoriasis patients treated with cyclosporine who have been previously treated with PUVA or methotrexate are at increased risk of skin cancer. Cyclosporine also increases the risk of lymphoma and predisposes patients to infection. More common side effects of cyclosporine include hypertrichosis, gum hyperplasia, and tremor.

Cyclosporine is a pregnancy category C drug. Limited experience in pregnant transplant recipients suggests that cyclosporine is not associated with fetal malformations but is associated with low-birthweight babies. Breast-feeding should be avoided in mothers on cyclosporine.

Tacrolimus

Mechanism of Action

Tacrolimus binds to the T-cell immunophilin FK-binding protein 12 (FKBP-12), and this complex inhibits activation of calcineurin (see Cyclosporine, Mechanism of Action). As with cyclosporine, tacrolimus also has calcineurin-independent inhibitory effects on the MAPK pathway. Tacrolimus is metabolized by CYP3A in the liver and is more than 90% excreted in feces. Drug interactions occur when tacrolimus is co-administered with inhibitors or inducers of CYP3A. Tacrolimus is given twice daily as a divided oral dose, with dose adjustments made based on trough levels.

Clinical Use

Tacrolimus is approved for the prevention of allogeneic kidney, heart, and liver transplant rejection, and graft survival is similar to that achieved with cyclosporine-based regimens. Tacrolimus should be used in combination with azathioprine or mycophenolate mofetil in heart and kidney transplant recipients.

Toxicity and Monitoring

Tacrolimus, particularly at high doses, can cause nephrotoxicity and hypertension and should not be used in combination with cyclosporine. Like cyclosporine, tacrolimus can also cause hyperkalemia, headache, and tremor, and it is associated with an increased risk of infections, lymphoma, and skin cancers. Tacrolimus is associated with new-onset type 2 diabetes in approximately 20% of transplant recipients, but it reverses in about one third of them by 1 year post-transplant. Tacrolimus has been associated with cardiac hypertrophy,

which is reversible upon dose reduction or drug discontinuation. Tacrolimus given by injection can be associated with anaphylaxis, likely due to castor oil derivatives contained in the IV formulation, and should be avoided unless oral administration is impossible.

Tacrolimus has not been associated with fetal malformations, but it has been associated with preterm birth, as well as hyperkalemia and renal impairment during pregnancy. Breast-feeding should be avoided in mothers taking tacrolimus.

Sirolimus

Mechanism of Action

Sirolimus, like tacrolimus, binds to the immunophilin FKBP-12. However, unlike tacrolimus, the sirolimus/FKBP-12 complex inhibits activation of the mammalian target of rapamycin (mTOR) and has no effect on calcineurin. mTOR inhibition blocks antigen- and cytokine-driven T-cell proliferation and also inhibits antibody production. mTOR is also an important modulator for aging and age-related diseases. mTOR inhibitors may have anticancer activity for many types of malignancies. Sirolimus is given once daily as an oral dose, and excretion is over 90% in feces. Sirolimus has a long half-life, and dose adjustments should not be more frequent than every 7 to 14 days, guided by trough levels. A loading dose more rapidly achieves therapeutic levels, both when sirolimus treatment is initiated and when dose adjustments are made. Like cyclosporine, sirolimus is a substrate for CYP3A4 and P-glycoprotein, and concomitant use of strong inducers or inhibitors of CYP3A4 or P-glycoprotein should be avoided when possible. When given concomitantly with cyclosporine, sirolimus should be administered 4 hours after cyclosporine to minimize their interaction. The dose of sirolimus often needs to be increased after cyclosporine is withdrawn.

Clinical Use

Sirolimus is approved for the prevention of allogeneic renal transplant rejection and is used in combination with cyclosporine and glucocorticoids starting at the time of transplant (Chapter 117). Cyclosporine can be withdrawn 3 to 12 months after transplant, depending on the patient's risk of rejection. Sirolumus is also approved for the treatment of patients with lympangioleiomyomatosis (Chapter 80).

Toxicity and Monitoring

Patients taking sirolimus are at increased risk of lymphoma and infection. Sirolimus can be associated with angioedema (particularly when used together with ACE inhibitors), fluid accumulation, and delayed wound healing. Sirolimus can be associated with renal insufficiency, particularly when used with cyclosporine, and the new onset of proteinuria. Patients on sirolimus can develop hyperlipidemia and are at risk for rhabdomyolysis when given HMG-CoA reductase inhibitors, particularly if they are receiving concomitant cyclosporine.

Sirolimus is contraindicated in pregnancy, given its antiproliferative effects. Breast-feeding should also be avoided in mothers taking sirolimus.

ALKYLATING AGENTS

Cyclophosphamide

Mechanism of Action

Cyclophosphamide is a prodrug that is metabolized in the liver by CYP-450 enzymes to alkylating molecules that cause DNA cross-linking. This occurs preferentially in rapidly proliferating cells, such as tumor and hematopoietic cells.

Clinical Use

Cyclophosphamide is approved for the treatment of a variety of malignancies, as well as minimal change nephrotic syndrome, but is also used in the treatment of lupus nephritis and antineutrophil cytoplasmic antibodies (ANCA)–associated vasculitis. The use of cyclophosphamide for these conditions has declined, however, as less toxic therapies, such as mycophenolate mofetil for lupus nephritis and rituximab for ANCA-associated vasculitis, have been shown to be equally efficacious.

Toxicity and Monitoring

Cyclophosphamide causes myelosuppression and predisposes patients to infections (including opportunistic ones), and cyclophosphamide metabolites can cause hemorrhagic cystitis. Cardiac toxicity is also seen. Cyclophosphamide increases the risk of secondary malignancies and increases the risk of bladder cancer even in patients who do not experience hemorrhagic cystitis during treatment. Cyclophosphamide commonly causes nausea and hair loss. Cyclophosphamide should not be used together with a TNF inhibitor because of an increased risk of solid tumors with this combination.

Cyclophosphamide can cause infertility, and the risk is higher the older the patient and the greater the cumulative cyclophosphamide dose. Treatment with a GnRH agonist prior to each dose of cyclophosphamide can help to protect gonadal function. Cyclophosphamide causes fetal malformations and miscarriages and should not be used in pregnancy or during lactation.

BIOLOGIC AGENTS AND SIGNALING INHIBITORS

NANCY J. OLSEN AND JOHN J. O'SHEA

Many of the drugs used by clinicians, even if effective and safe, were discovered empirically, meaning their molecular target was not necessarily known in advance. By comparison, therapeutic agents derived from biologic molecules and other targeted therapies have transformed many areas of medicine over the past two decades. A significant advantage of this new type of drug is the possibility of acting on specific molecules directly involved in disease pathogenesis. The concept of targeted agents carried with it the promise of reduced toxicity compared to empirically generated agents. Although this promise may not have been universally fulfilled, most targeted drugs have relatively good margins of safety and their usage in many areas of medicine has steadily increased. The efficacy (or lack thereof) of targeted therapies has also contributed to understanding of disease mechanisms.

Targeted therapeutics can be broadly classified as "biologics," meaning that they are produced from natural sources or living organisms. In this chapter though, we will be focusing on products engineered to be produced by cells using biotechnology methods. In general, these are large molecules administered by intravenous or subcutaneous routes. Newer additions to this class are small molecules synthesized and designed for specific targets. The targeting of specific signaling pathways was challenging given the similarities of some of these molecules, such as kinases, which may contribute to many intracellular processes. Nevertheless, many of these obstacles have been successfully overcome, resulting in a class of novel therapeutics.

Targeted therapies such as biologic agents and signaling inhibitors have applications in many areas of medicine, including cancer as well as immune-mediated dermatologic, rheumatologic, infectious, neurologic, hematologic, and cardiovascular disease. The range of possible and approved indications is almost endless and will continue to be an area of intense research and development.

BIOLOGIC AGENTS

Several types of biologics have been used as targeted therapies (Table 29-1; Fig. 29-1). One widely used class of drugs is recombinant proteins, including cytokines, interferons, growth factors, and colony-stimulating factors. Examples include granulocyte colony-stimulating factor (G-CSF; filgrastim, lenograstim), used to treat neutropenia, and interleukin (IL)-2 (aldesleukin), approved for treatment of melanoma and renal cell carcinoma. Classic endocrine mediators that engage receptors and activate intracellular signaling pathways, such as growth hormone, can be considered in this category as well (Chapter 205).

which is reversible upon dose reduction or drug discontinuation. Tacrolimus given by injection can be associated with anaphylaxis, likely due to castor oil derivatives contained in the IV formulation, and should be avoided unless oral administration is impossible.

Tacrolimus has not been associated with fetal malformations, but it has been associated with preterm birth, as well as hyperkalemia and renal impairment during pregnancy. Breast-feeding should be avoided in mothers taking tacrolimus.

Sirolimus

Mechanism of Action

Sirolimus, like tacrolimus, binds to the immunophilin FKBP-12. However, unlike tacrolimus, the sirolimus/FKBP-12 complex inhibits activation of the mammalian target of rapamycin (mTOR) and has no effect on calcineurin. mTOR inhibition blocks antigen- and cytokine-driven T-cell proliferation and also inhibits antibody production. mTOR is also an important modulator for aging and age-related diseases. mTOR inhibitors may have anticancer activity for many types of malignancies. Sirolimus is given once daily as an oral dose, and excretion is over 90% in feces. Sirolimus has a long half-life, and dose adjustments should not be more frequent than every 7 to 14 days, guided by trough levels. A loading dose more rapidly achieves therapeutic levels, both when sirolimus treatment is initiated and when dose adjustments are made. Like cyclosporine, sirolimus is a substrate for CYP3A4 and P-glycoprotein, and concomitant use of strong inducers or inhibitors of CYP3A4 or P-glycoprotein should be avoided when possible. When given concomitantly with cyclosporine, sirolimus should be administered 4 hours after cyclosporine to minimize their interaction. The dose of sirolimus often needs to be increased after cyclosporine is withdrawn.

Clinical Use

Sirolimus is approved for the prevention of allogeneic renal transplant rejection and is used in combination with cyclosporine and glucocorticoids starting at the time of transplant (Chapter 117). Cyclosporine can be withdrawn 3 to 12 months after transplant, depending on the patient's risk of rejection. Sirolumus is also approved for the treatment of patients with lympangioleiomyomatosis (Chapter 80).

Toxicity and Monitoring

Patients taking sirolimus are at increased risk of lymphoma and infection. Sirolimus can be associated with angioedema (particularly when used together with ACE inhibitors), fluid accumulation, and delayed wound healing. Sirolimus can be associated with renal insufficiency, particularly when used with cyclosporine, and the new onset of proteinuria. Patients on sirolimus can develop hyperlipidemia and are at risk for rhabdomyolysis when given HMG-CoA reductase inhibitors, particularly if they are receiving concomitant cyclosporine.

Sirolimus is contraindicated in pregnancy, given its antiproliferative effects. Breast-feeding should also be avoided in mothers taking sirolimus.

ALKYLATING AGENTS

Cyclophosphamide

Mechanism of Action

Cyclophosphamide is a prodrug that is metabolized in the liver by CYP-450 enzymes to alkylating molecules that cause DNA cross-linking. This occurs preferentially in rapidly proliferating cells, such as tumor and hematopoietic cells.

Clinical Use

Cyclophosphamide is approved for the treatment of a variety of malignancies, as well as minimal change nephrotic syndrome, but is also used in the treatment of lupus nephritis and antineutrophil cytoplasmic antibodies (ANCA)–associated vasculitis. The use of cyclophosphamide for these conditions has declined, however, as less toxic therapies, such as mycophenolate mofetil for lupus nephritis and rituximab for ANCA-associated vasculitis, have been shown to be equally efficacious.

Toxicity and Monitoring

Cyclophosphamide causes myelosuppression and predisposes patients to infections (including opportunistic ones), and cyclophosphamide metabolites can cause hemorrhagic cystitis. Cardiac toxicity is also seen. Cyclophosphamide increases the risk of secondary malignancies and increases the risk of bladder cancer even in patients who do not experience hemorrhagic cystitis during treatment. Cyclophosphamide commonly causes nausea and hair loss. Cyclophosphamide should not be used together with a TNF inhibitor because of an increased risk of solid tumors with this combination.

Cyclophosphamide can cause infertility, and the risk is higher the older the patient and the greater the cumulative cyclophosphamide dose. Treatment with a GnRH agonist prior to each dose of cyclophosphamide can help to protect gonadal function. Cyclophosphamide causes fetal malformations and miscarriages and should not be used in pregnancy or during lactation.

BIOLOGIC AGENTS AND SIGNALING INHIBITORS

NANCY J. OLSEN AND JOHN J. O'SHEA

Many of the drugs used by clinicians, even if effective and safe, were discovered empirically, meaning their molecular target was not necessarily known in advance. By comparison, therapeutic agents derived from biologic molecules and other targeted therapies have transformed many areas of medicine over the past two decades. A significant advantage of this new type of drug is the possibility of acting on specific molecules directly involved in disease pathogenesis. The concept of targeted agents carried with it the promise of reduced toxicity compared to empirically generated agents. Although this promise may not have been universally fulfilled, most targeted drugs have relatively good margins of safety and their usage in many areas of medicine has steadily increased. The efficacy (or lack thereof) of targeted therapies has also contributed to understanding of disease mechanisms.

Targeted therapeutics can be broadly classified as "biologics," meaning that they are produced from natural sources or living organisms. In this chapter though, we will be focusing on products engineered to be produced by cells using biotechnology methods. In general, these are large molecules administered by intravenous or subcutaneous routes. Newer additions to this class are small molecules synthesized and designed for specific targets. The targeting of specific signaling pathways was challenging given the similarities of some of these molecules, such as kinases, which may contribute to many intracellular processes. Nevertheless, many of these obstacles have been successfully overcome, resulting in a class of novel therapeutics.

Targeted therapies such as biologic agents and signaling inhibitors have applications in many areas of medicine, including cancer as well as immune-mediated dermatologic, rheumatologic, infectious, neurologic, hematologic, and cardiovascular disease. The range of possible and approved indications is almost endless and will continue to be an area of intense research and development.

BIOLOGIC AGENTS

Several types of biologics have been used as targeted therapies (Table 29-1; Fig. 29-1). One widely used class of drugs is recombinant proteins, including cytokines, interferons, growth factors, and colony-stimulating factors. Examples include granulocyte colony-stimulating factor (G-CSF; filgrastim, lenograstim), used to treat neutropenia, and interleukin (IL)-2 (aldesleukin), approved for treatment of melanoma and renal cell carcinoma. Classic endocrine mediators that engage receptors and activate intracellular signaling pathways, such as growth hormone, can be considered in this category as well (Chapter 205).

ABSTRACT

Therapeutics derived from biologic molecules have transformed many areas of medicine. The development of these new agents is a major shift from previous, largely empirical, approaches to drug development. Biologics, including monoclonal antibodies, recombinant and fusion proteins, and engineered cells, are designed to target pathways involved in disease pathogenesis from cancer and autoimmunity to cardiovascular, neurologic, and infectious disease. In recent years, small molecule inhibitors of intracellular signaling pathways have been added to the list of available targeted therapeutics. Many of these drugs also have been shown in rigorous clinical trials to have efficacy and safety in the treatment of a wide range of conditions ranging from malignancies to autoimmune diseases. This chapter will discuss specific agents in these broad categories, focusing on approved treatments and using selected examples to illustrate molecular targets, mechanisms, and clinical applications. This is a fast-moving area with great potential for even wider clinical applications in the future.

KEYWORDS

biologic agents
signaling inhibitors
monoclonal antibodies
cytokines
growth factors
targeted therapies

In addition to cytokines, humans produce endogenous cytokine antagonists. An example is anakinra, which is a recombinant version of a naturally occurring protein, the IL-1 receptor antagonist. The drug, like the natural protein, blocks binding of IL-1 to its receptor, thereby preventing signaling. It differs from the native human protein by the addition of one terminal amino acid. It is approved to treat rheumatoid arthritis (Chapter 243) and some childhood inflammatory syndromes.

Many of the commonly used biologics are monoclonal antibodies, which were initially derived from mice using hybridoma technology. By comparison, chimeric immunoglobulins are engineered to have murine variable regions of the component heavy and light chains attached to human constant regions. An example is infliximab, which targets the cytokine tumor necrosis factor-α (TNF-α). However, antichimeric antibodies develop in some treated patients and have the potential to block their efficacy. Further refinements using phage display techniques led to development of completely humanized monoclonal immunoglobulin Gs (IgGs); the TNF-α–targeting product adalimumab was an early example. More than 100 monoclonal antibodies have now been approved for diverse indications.[1]

A variation on monoclonal antibody therapy is the creation of antibody drug conjugates, meaning that other moieties, including small molecules, are chemically linked to the antibodies; examples include brentuximab vedotin and trastuzumab emtansine. The former is used in Hodgkin's lymphoma (Chapter 172) and targets CD30 with an antibody coupled to monomethyl auristatin E to effect cell killing. The latter targets *HER2* on cancer cells by the antibody and kills the cells with its "warhead."

Another approach to designing biologic therapeutics is with fusion proteins. Most of these agents are receptors that are fused to other human proteins like the Fc portion of immunoglobulins. These agents may target soluble or cell-bound molecules such as cytokines by functioning as decoy receptors that prevent binding of the mediator to its receptor. The first major therapeutic application of this technology was etanercept, which combines the human TNF-α receptor with a human Fc portion of the IgG molecule. An alternative strategy is to graft biologically active peptides onto the Fc domain of IgG, as in romiplostim, a thrombopoietin receptor agonist, approved for treatment of immune thrombocytopenia (Chapter 158). Cytokine fusion molecules also can be created. An example is IL-2 linked to a peptide of diphtheria toxin that was

TABLE 29-1 CLASSES OF BIOTHERAPEUTICS

CLASS	TYPES	EXAMPLES
Recombinant proteins	Cytokines Growth factors IL-1 receptor antagonist	Aldesleukin (IL-2) Filgrastim Anakinra
Monoclonal antibodies	Murine Chimeric Humanized	OKT3 Infliximab Adalimumab
Antibody-drug conjugates	Tumor cytotoxics	Brentuximab vedotin
Fusion proteins	Decoy receptors Immunotoxins	Etanercept Denileukin diftitox
Engineered cells	CAR-T cells	Tisagenlecleucel

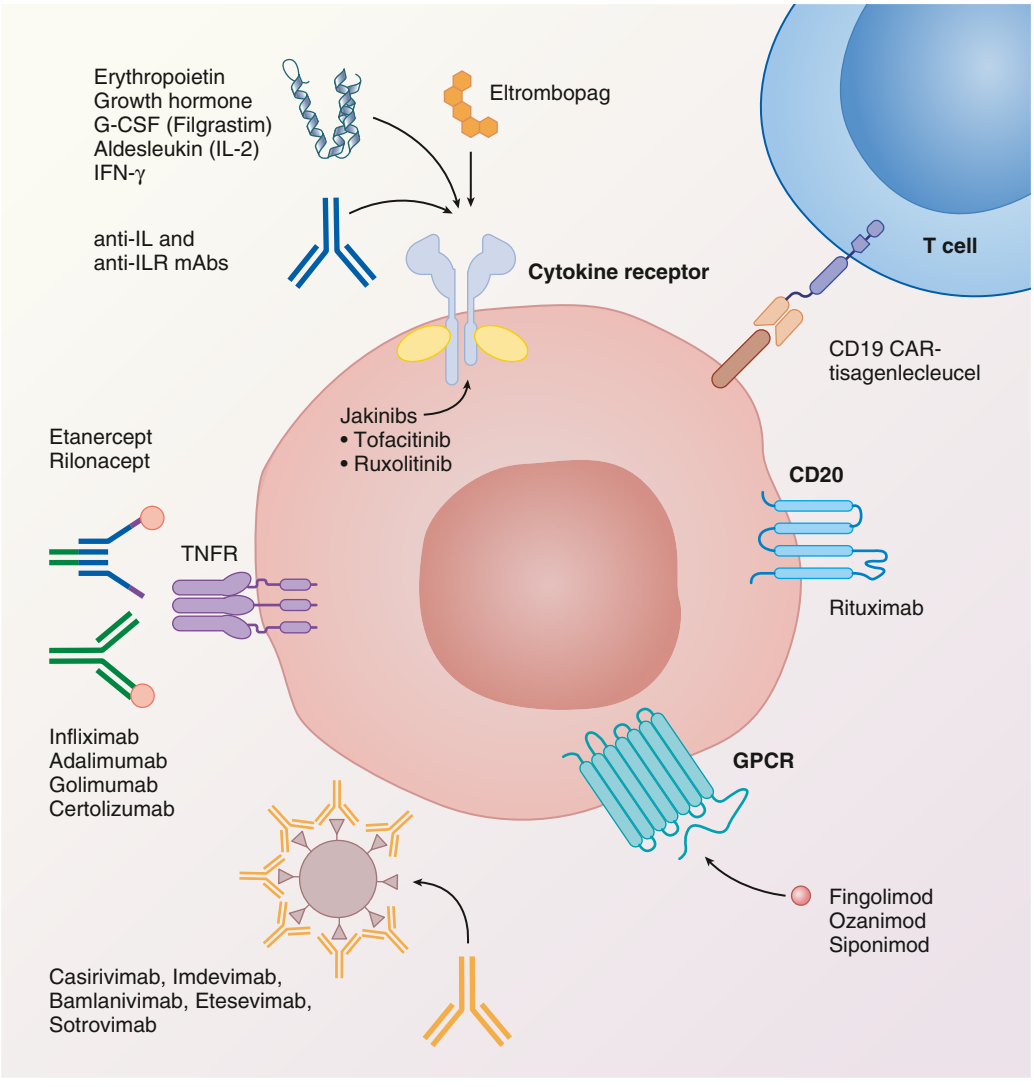

FIGURE 29-1. Biologics and signaling inhibitors that have clinical applications as targeted therapeutics take many forms. Recombinant cytokines and growth factors, monoclonal antibodies, and fusion proteins may target small molecules or cells. Newer approaches include cells that are engineered to target tumors and small molecular weight kinase inhibitors that block intracellular signaling pathways. The clinical applications of these therapies are numerous, ranging from malignancies to autoimmune diseases. CAR = chimeric T cell antigen receptor; G-CSF = granulocyte colony-stimulating factor; GPCR = G protein–coupled receptor; IFN = interferon; IL = interleukin; ILR = interleukin receptor; TNFR = tumor necrosis factor receptor.

approved for treatment of cutaneous T-cell lymphoma but was subsequently removed from the market because of toxicities, especially visual loss.

A more recently developed class of biologics is engineered cells. Perhaps the most exciting example of this therapy is chimeric antigen receptor (CAR)-T cells.[2,3] Such cells are a remarkable example of gene therapy in which T cells are directed to tumor cells by transduction with engineered antigen receptors. Approved CAR-T cells include tisagenlecleucel, axicabtagene ciloleucel, and lisocabtagene maraleucel, all of which target malignant B cells and represent the first examples of engineered living cells being approved.

SPECIFIC TYPES OF BIOLOGIC AGENTS

Biologic agents also can be considered in groups defined by their corresponding targets. Examples include soluble mediators (e.g., cytokines, complement proteins, antibodies, and growth factors), viruses,[4] and cells (including malignant cells and normal cells, especially T and B lymphocytes).

BIOLOGICS THAT TARGET SOLUBLE PROTEINS

Cytokines

The cytokine TNF-α binds to two receptors (TNFR55 and TNFR75), where it contributes to host responses against infection. When TNF-α production is uncontrolled, chronic inflammation can cause subsequent tissue damage in diseases such as rheumatoid arthritis (Chapter 243). Both monoclonal antibodies and soluble TNF-α receptor molecules are efficacious in inhibiting the activity of TNF-α (Table 29-2). These biologics all neutralize soluble TNF-α, but the monoclonal antibodies are more effective at also binding and preventing signaling of transmembrane forms of the cytokine. Efficacy of these approved biologics in rheumatoid arthritis and other conditions was shown in large, randomized, placebo-controlled trials in combination with methotrexate or as monotherapy.[A1,A2] However, these agents are not completely interchangeable,[5] as shown by the lack of utility of etanercept in treatment of granulomatous diseases such as Crohn disease (Chapter 127), for which infliximab is efficacious.[A3] Adverse effects of TNF blockade include an increased risk of infection, especially reactivation of latent tuberculosis, and therefore screening tests to exclude tuberculosis are required before its use.

RANKL, which is another member of the TNF superfamily, promotes osteoclast differentiation and bone resorption. Denosumab is a recombinant human monoclonal antibody that targets RANKL, which interferes with differentiation, activation, and survival of osteoclasts. It is indicated for treatment of postmenopausal osteoporosis (Chapter 225) and in men and women at high risk of bone loss after treatment with androgen deprivation therapy or aromatase inhibitors, respectively. Conversely, sclerostin, which is a product of osteocytes, inhibits bone formation; romosozumab targets sclerostin and is approved for the treatment of postmenopausal osteoporosis.

B cell activating factor (BAFF, aka Blys, CD257) is also in the TNF family. Belimumab is an anti-BAFF monoclonal antibody approved to treat adults with active systemic lupus erythematosus (Chapter 245). A fusion protein targeting CD257, blisibimod, is being investigated as a treatment for IgA nephropathy (Chapter 107).

IL-1 is an important driver of fever and induction of acute phase protein synthesis. Three approved therapeutics for IL-1 blockade are available at this time (Table 29-2): recombinant human IL-1 receptor antagonist (anakinra), a receptor fusion molecule (rilonacept) displaying both the IL-1 receptor and the IL-1 receptor accessory protein, and a fully human monoclonal antibody against IL-1β (canakinumab). Efficacy of anakinra in adult rheumatoid arthritis was somewhat disappointing, but subsequent studies in children with inflammatory arthritis showed significant therapeutic effects. It has become clear that IL-1β is the key inflammatory mediator of the autoinflammatory syndromes (Chapter 240), and IL-1 blockade using these agents has been approved for treatment of these conditions. An advantage of IL-1 blockade is a lower risk of infections than with TNF-α inhibitors. Canakinumab also has been shown to prevent recurrent cardiovascular events in patients who have suffered a myocardial infarction and who have elevated C-reactive protein (CRP) levels (Chapter 58).

Daclizumab, a humanized monoclonal IgG1 that targets the high-affinity IL-2 receptor by binding IL-2R alpha chain is approved for the prevention of acute renal transplant rejection but was discontinued in 2009. In 2016 it was approved for relapsing forms of multiple sclerosis (Chapter 380).

Dupilumab binds to the alpha chain subunit that is shared by the IL-4 and IL-13 receptors and inhibits signaling of both of these type 2 cytokines. It is approved for treatment of atopic dermatitis, asthma, and rhinosinusitis with polyps.

TABLE 29-2 APPROVED BIOTHERAPEUTICS TARGETING TNF-α, INTERLEUKIN-1, AND INTERLEUKIN-6

TARGET	THERAPEUTIC	DESCRIPTION	APPROVED INDICATIONS
TNF-α	Infliximab	Chimeric mAb	Rheumatoid arthritis, psoriatic arthritis, psoriasis, ankylosing spondylitis, Crohn disease
	Etanercept	Receptor fusion molecule	Rheumatoid arthritis, psoriatic arthritis, psoriasis, ankylosing spondylitis, polyarticular juvenile idiopathic arthritis
	Adalimumab	Humanized mAb	Rheumatoid arthritis, psoriasis, hidradenitis suppurativa, adult and pediatric Crohn disease, ankylosing spondylitis, polyarticular juvenile idiopathic arthritis
	Golimumab	Human IgG1 mAb	Rheumatoid arthritis, psoriatic arthritis, ankylosing spondylitis, ulcerative colitis
	Certolizumab pegol	Pegylated Fab′ fragment of a mAb	Rheumatoid arthritis, psoriatic arthritis, Crohn disease
IL-1	Anakinra	Recombinant human IL-1 receptor antagonist	Rheumatoid arthritis, cryopyrin-associated periodic syndromes
	Rilonacept	Recombinant receptor fusion molecule	Cryopyrin-associated periodic syndromes
	Canakinumab	Human IgG1 mAb	Systemic juvenile idiopathic arthritis, adult and pediatric familial Mediterranean fever, TNF receptor-associated periodic syndrome, hyper IgD syndrome
IL-6	Tocilizumab	Recombinant humanized mAb	Rheumatoid arthritis, giant cell arteritis, systemic juvenile idiopathic arthritis, polyarticular juvenile idiopathic arthritis
	Sarilumab	Human IgG1 mAb	Rheumatoid arthritis

IgD = immunoglobulin D; IgG = immunoglobulin G; IL = interleukin; mAb = monoclonal antibody; TNF = tumor necrosis factor.

IL-5 is important for eosinophil maturation and activation. Three anti-IL-5 monoclonal antibodies, mepolizumab, reslizumab, and benralizumab are approved for the treatment of asthma (Chapter 75) and eosinophilia (Chapter 156).

Similar to IL-1, IL-6 is a prototypic inflammatory cytokine, which drives production of TNF-α, IL-1, and IL-17.[6] Therapeutic blockade of IL-6R with tocilizumab and sarilumab is approved for treatment of inflammatory joint conditions in adults and children (Table 29-2). Subcutaneous tocilizumab is approved for the treatment of giant cell arteritis (Chapter 250). Tocilizumab use is associated with increased risk of varicella zoster virus infection as well as liver and cholesterol abnormalities. Satralizumab is an IL-6R monoclonal antibody approved for neuromyelitis optica (Chapter 392). Siltuximab is an IL-6 antibody approved for multicentric Castleman disease (Chapter 171).

IL-12 and IL-23 are dimeric cytokines that share a subunit (p40). Ustekinumab targets this common p40 chain, preventing binding of both cytokines to their corresponding receptors, which are expressed primarily on activated T cells. Ustekinumab is an approved treatment for psoriasis (Chapter 405), psoriatic arthritis (Chapter 244), and Crohn disease (Chapter 127). Agents that target the p19 subunit of IL-23, including guselkumab, tildrakizumab, and risankizumab are approved for the treatment of psoriasis and psoriatic arthritis.

The IL-17 family includes 6 members, with IL-17A and IL-17F sharing sequence similarities and having the greatest role in development of autoimmunity. Neutralizing antibodies to IL-17A (secukinumab and ixekizumab) and IL-17R (brodalumab) are approved by the U.S. Food and Drug Administration to treat ankylosing spondylitis, psoriasis, and psoriatic arthritis.[A4,7]

Interferons are important for host defense, especially against viruses but are overexpressed in autoimmune disease, particularly systemic lupus erythematosus. Anifrolumab binds to IFN-alpha receptor 1 (IFNAR1) and thereby blocks IFN-α and IFN-β. In phase III trials, anifrolumab reduced lupus disease activity, improved skin rash and arthritis, and reduced corticosteroid use. It is now approved for treatment of moderate or severe systemic lupus erythematosus.[A5] Emapalumab targets IFN-γ and is approved for hematophagocytic lymphohistiocytosis (Chapter 155).[8]

Thymic stromal lymphopoietin (TSLP) is an epithelial-derived cytokine that has a role in allergic disease, upregulates other cytokines and is elevated in the airways of patients with asthma. A recent phase II trial showed efficacy of an anti-TSLP monoclonal antibody, tezepelumab, in patients with noneosinophilic asthma.

Antibodies

IgE antibodies mediate allergic diseases by binding through the Fc portion of the molecule to specific receptors, FcεRI and CD23/FcεRII. Omalizumab is an approved humanized IgG1 monoclonal antibody that binds free IgE and prevents receptor binding and signaling. Indications for treatment with omalizumab include allergic asthma that has failed other therapies and chronic spontaneous urticaria (Chapter 232). Because of the elevated risk of allergic reactions, subcutaneous injections of this drug must be administered in a medical office rather than in the home.

Complement

Tissue damage in allergic and immune disorders is often mediated by complement proteins, so targeting these molecules is a useful therapeutic approach. Eculizumab and ravulizumab are anti-C5 monoclonal antibodies that prevent the formation of the membrane attack complex and block chemotactic activity of C5a. They are approved to treat paroxysmal nocturnal hemoglobinuria (Chapter 146) and are available in some countries for the treatment of atypical hemolytic uremic syndrome. Investigational applications include age-related macular degeneration. An inhibitor of C5a, avacopan, is being investigated for treatment of antineutrophil cytoplasm antibody (ANCA)-associated vasculitis.[A6]

BIOLOGIC AGENTS THAT TARGET CELLS

B Lymphocytes

The humoral arm of the immune response mediates many autoimmune disorders through production of autoantibodies. Therefore, blockade or targeted elimination of B lymphocytes and inhibition of B cell–derived cytokines has been used therapeutically in diseases such as systemic lupus erythematosus (Chapter 245) and rheumatoid arthritis.[9] Rituximab is a chimeric monoclonal antibody that targets CD20 B cells for deletion. It was first used for treatment of B-cell lymphomas (Chapter 171) and is now also approved for treatment of rheumatoid arthritis. Consensus documents also suggest that rituximab may be useful as treatment for organ-damaging systemic lupus erythematosus that has failed other therapies. Ocrelizumab is a humanized monoclonal antibody that targets an overlapping epitope of CD20 and is an FDA-approved treatment for multiple sclerosis (Chapter 380). Obinutuzumab and ofatumumab are anti-CD20 monoclonal antibody approved for lymphoma and being studied for autoimmune disease. Targeting CD19 rather than CD20 is of interest as an alternative approach because of the potential for depleting long-lived plasma cells and early B cells that are not CD20-positive, while at the same time sparing regulatory B cells. Anti-CD19 antibodies are currently in trials for autoimmune diseases and malignancies. Blinatumomab is a bispecific agent that targets CD3 on T cells and CD19 on B cells and is approved for acute lymphoblastic leukemia (Chapter 168).

T Lymphocytes

The central role of T lymphocytes in the immune response makes this cell subset an attractive target for treatments of autoimmune disease and graft rejection as well as cancer immunotherapy. Therapies targeting the T-cell surface marker CD3 have been available for several decades and are still in limited use for the treatment of transplant rejection. The first humanized therapeutic monoclonal antibody was alemtuzumab, which targeted the CD52 molecule on T and B lymphocytes. An unexpected and as yet unexplained consequence of this treatment was long-standing lymphopenia, limiting its use. Ibalizumab is anti-CD4 monoclonal antibody for treatment of human immunodeficiency virus (HIV).

Costimulatory and Checkpoint Molecules

Another approach is inhibition of costimulatory signals required for full T-cell activation. The best example is the fusion protein abatacept, in which the extracellular portion of cytotoxic T lymphocyte antigen-4 (CTLA-4) is coupled to the extracellular portion of human IgG1. This molecule, which inhibits costimulatory signals between CD28 and CD80/86, is FDA approved for the treatment of rheumatoid arthritis (Chapter 243). Addition of abatacept to cyclophosphamide, however, did not improve the outcome of lupus nephritis in a trial. In general, infectious complications associated with abatacept are lower than with drugs that block TNF-α. Physiologically, CTLA4 binds CD80/CD86 and delivers a signal that inhibits T-cell activation. Antibodies that target CTLA4 and other negative regulators of T-cell activation (PD1, PDL1) represent a new class of drugs, checkpoint inhibitors, that are currently in use to treat various cancers (Chapter 164).[10] Examples include ipilimumab, nivolumab, atezolizumab, pembrolizumab, cemiplimab, avelumab, and durvalumab. Checkpoint inhibitors may induce immune-related adverse effects and can exacerbate autoimmune diseases.[11]

Adhesion Molecules

Another way to manipulate T cells in the immune response is to block migration to sites of inflammation. Natalizumab, which is a human monoclonal antibody against α_4-integrin, achieves this effect and is approved to treat relapsing/remitting forms of multiple sclerosis. A safety concern with natalizumab is the risk of progressive multifocal leukoencephalopathy (Chapter 341), a fatal condition associated with reactivation of the JC virus in immunosuppressed individuals. Vedolizumab is a monoclonal antibody that targets α4β7 integrin and is approved for ulcerative colitis and Crohn disease.[A7]

Growth Factor Receptors

Growth factor receptors, also known as receptor tyrosine kinases, are key regulators of normal cellular function but can also have major roles in cancer. Multiple monoclonal antibodies that target epidermal growth factor receptors (EGFRs) are approved, including trastuzumab and pertuzumab (breast cancer; Chapter 183); cetuximab and panitumumab (colorectal cancer; Chapter 179); and necitumumab (small cell lung cancer).

The vascular endothelial growth factor (VEGF) family of growth factors is involved in angiogenesis and has been implicated in pathogenesis of malignant disease, the development of metastases, and in forms of retinopathy. Bevacizumab and ramucirumab are biologics that target VEGF to treat malignancies including metastatic colon cancer (Chapter 179). VEGF inhibitors ramucirumab, brolucizumab, and ranibizumab are approved for treatment of macular degeneration (Chapter 391). Another approach to targeting VEGF is with the recombinant fusion protein aflibercept, which is composed of binding domains of the two human receptors for VEGF fused to human IgG1 Fc.

Other Therapeutic Targets Engaged By Monoclonal Antibodies

Aside from cancer, autoimmunity, and allergic disease, biologics are used in the treatment of a wide variety of additional disorders. For instance, the proprotein convertase subtilisin/kexin type 9 (PCSK9) binds to low-density lipoprotein (LDL) receptors and facilitates their degradation. The PSCK9 monoclonal antibodies alirocumab and evolocumab promote recycling LDL receptors and are approved for treatment of hypercholesterolemia (Chapter 190). Caplacizumab is a monoclonal antibody that targets von Willebrand factor and is used for the treatment of acquired thrombocytopenic purpura (Chapter 158). Crizanlizumab targets P-selectin approved for vaso-occlusive crisis in sickle cell disease, and lanadelumab targets kallikrein for treatment of hereditary angioedema (Chapter 232). Litifilimab, a monoclonal antibody to blood dendritic cell antigen 2 (BDCA2), has shown potential for the treatment of cutaneous lupus erythematosus.[A8]

Calcitonin gene–related peptide (CGRP) is a potent vasodilator involved in the pathophysiology of migraine (Chapter 367). Galcanezumab and fremanezumab target CGRP and erenumab targets CGRP receptor for migraine prevention. Aducanumab binds aggregated amyloid β and is approved for the treatment of Alzheimer disease, although controversy remains regarding its efficacy and cost-effectiveness (Chapter 371).

Biologics are also used in the treatment of infectious disease. Raxibacumab is a monoclonal antibody directed against the protective antigen component of lethal toxin of *Bacillus anthracis* (Chapter 272). Palivizumab is a monoclonal antibody that binds the F protein of respiratory syncytial virus (Chapter 330) and is used to prevent severe disease. For severe acute respiratory syndrome coronavirus 2, antispike monoclonal antibodies, including casirivimab, imdevimab, bamlanivimab, etesevimab, and sotrovimab, have been used for prevention and treatment (Chapter 337).

SMALL MOLECULE TARGETED THERAPIES

In addition to recombinant cytokines, small molecule agonists of cytokine receptors have been generated. Eltrombopag is a small molecule thrombopoietin receptor agonist that is approved for treatment of cases of immune thrombocytopenia (ITP) that are resistant to other therapies. It has the advantage of oral dosing (Chapter 158). The original approval for ITP was subsequently expanded with addition of severe aplastic anemia (Chapter 151), in which efficacy is due to actions on stem cells that result in production of other cell lines. This interesting precedent suggests that many other small molecule cytokine receptor agonists and antagonists might be useful therapeutics.

Seven-transmembrane receptors, including chemokine receptors, are very "druggable" targets. Two examples of drugs that target chemokine receptors include maraviroc, a small, orally available molecule that targets the chemokine receptor CCR5. This receptor is an essential cofactor for HIV entry into the cell, which is the mechanism of its antiretroviral effects. Fingolimod, ozanimod, and siponimod are small molecule receptor modulators that target sphingosine-1-phosphate receptor (S1PR1), which is critical for trafficking of T cells and vascular integrity. These agents are approved for multiple sclerosis, and ozanimod is also approved for treatment of ulcerative colitis.[12]

SIGNALING INHIBITORS

An alternative to targeting cytokines extracellularly is to use small molecules that block intracellular signaling pathways activated by binding of cytokines to their specific receptors. An advantage of this approach is that the drugs are administered orally. Because of the ultimately similar downstream cytokine targets, a basic safety principle is that biologics and signaling inhibitors are generally not recommended for use in combination. Janus kinases (JAKs) are critical for signaling by a large family of cytokines, presenting an especially attractive therapeutic target.[13,14] First-generation JAK inhibitors, or jakinibs, inhibit multiple JAKs and thus a large number of cytokines (Table 29-3). Jakinibs are approved for the treatment of rheumatoid arthritis, psoriatic arthritis, juvenile arthritis, and ulcerative colitis and are being investigated for the treatment of a number of other autoimmune and dermatologic conditions.[15,16] Polycythemia vera and related myeloproliferative neoplasms are due to gain-of-function *JAK2* mutations. Ruxolitinib inhibits JAK1 and JAK2 and is approved for the treatment of myeloproliferative neoplasms (Chapter 152) and acute graft-versus-host disease. First-generation jakinibs inhibit JAK2, which mediates signaling of many cytokines, including growth hormone, erythropoietin, thrombopoietin, IL-11, granulocyte colony-stimulating factor (G-CSF), and granulocyte macrophage (GM)-CSF; as a result, treated patients may develop anemia and other cytopenias. Although these effects are not usually severe enough to lead to discontinuation of treatment, newer selective jakinibs are being developed that spare JAK2.

Bruton tyrosine kinase has a critical role in B-cell function.[17] The Bruton tyrosine kinase inhibitors ibrutinib, acalabrutinib, and zanubrutinib are FDA approved to treat chronic lymphocytic leukemia (Chapter 169), Waldenström macroglobulinemia, and lymphoma. In all, more than 35 kinase inhibitors have been approved for multiple indications, including many cancers.

CONCLUSION

The use of biologic agents and signaling inhibitors has led to major improvements in the treatment of a wide variety of diseases, ranging from autoimmunity to malignancies. These targeted therapies have also provided insights into basic pathogenetic mechanisms in many of these disorders. Future directions are likely to focus on improved targeting, with greater selectivity for disease processes while sparing normal pathways, thereby reducing off-target effects. Expansion into other areas of medicine is also likely, with borrowed, modified, or completely new agents.

TABLE 29-3 APPROVED JANUS KINASE INHIBITORS

DRUG	TARGET	INDICATION
Ruxolitinib	JAK1/JAK2	MPN, acute GvHD
Tofacitinib	JAK1/JAK2/JAK3	RA, PsA, UC, polyarticular JIA
Baricitinib	JAK1/JAK2	RA, COVID-19 (EU)
Upadacitinib	JAK1	RA
Filgotinib	JAK1	RA (approved in EU, Japan)
Peficitinib	Multiple JAKs	RA (approved in Japan, Korea)
Fedratinib	JAK2/FLT3/RET/BRD4	MPN

COVID = coronavirus disease; EU = European Union; GvHD = graft versus host disease; JIA = juvenile idiopathic arthritis; MPN = myeloproliferative neoplasms; PsA = psoriatic arthritis; RA = rheumatoid arthritis; UC = ulcerative colitis.

30 COMPLEMENTARY AND INTEGRATIVE MEDICINE

FREDERICK M. HECHT

In addition to the pharmaceutical and surgical therapies that have been central to advances in medical care, a large proportion of people across the globe also use health care treatments that fall outside of conventional medical care. The United States' National Center for Complementary and Integrative Health of the National Institutes of Health has defined complementary health care as "health care approaches developed outside of mainstream Western, or conventional, medicine" when they are used together with conventional medicine, and as alternative medicine when they are used in place of conventional medicine. Integrative medicine is an approach to medical practice that includes conventional medical therapies as well as nonpharmaceutical and nonsurgical therapies that have not always been incorporated or emphasized in conventional medicine but for which some evidence base now exists. This approach typically includes the use of lifestyle, mind-body practices, or natural products. Because these therapies typically receive little or no attention during medical

Biologics are also used in the treatment of infectious disease. Raxibacumab is a monoclonal antibody directed against the protective antigen component of lethal toxin of *Bacillus anthracis* (Chapter 272). Palivizumab is a monoclonal antibody that binds the F protein of respiratory syncytial virus (Chapter 330) and is used to prevent severe disease. For severe acute respiratory syndrome coronavirus 2, antispike monoclonal antibodies, including casirivimab, imdevimab, bamlanivimab, etesevimab, and sotrovimab, have been used for prevention and treatment (Chapter 337).

SMALL MOLECULE TARGETED THERAPIES

In addition to recombinant cytokines, small molecule agonists of cytokine receptors have been generated. Eltrombopag is a small molecule thrombopoietin receptor agonist that is approved for treatment of cases of immune thrombocytopenia (ITP) that are resistant to other therapies. It has the advantage of oral dosing (Chapter 158). The original approval for ITP was subsequently expanded with addition of severe aplastic anemia (Chapter 151), in which efficacy is due to actions on stem cells that result in production of other cell lines. This interesting precedent suggests that many other small molecule cytokine receptor agonists and antagonists might be useful therapeutics.

Seven-transmembrane receptors, including chemokine receptors, are very "druggable" targets. Two examples of drugs that target chemokine receptors include maraviroc, a small, orally available molecule that targets the chemokine receptor CCR5. This receptor is an essential cofactor for HIV entry into the cell, which is the mechanism of its antiretroviral effects. Fingolimod, ozanimod, and siponimod are small molecule receptor modulators that target sphingosine-1-phosphate receptor (S1PR1), which is critical for trafficking of T cells and vascular integrity. These agents are approved for multiple sclerosis, and ozanimod is also approved for treatment of ulcerative colitis.[12]

SIGNALING INHIBITORS

An alternative to targeting cytokines extracellularly is to use small molecules that block intracellular signaling pathways activated by binding of cytokines to their specific receptors. An advantage of this approach is that the drugs are administered orally. Because of the ultimately similar downstream cytokine targets, a basic safety principle is that biologics and signaling inhibitors are generally not recommended for use in combination. Janus kinases (JAKs) are critical for signaling by a large family of cytokines, presenting an especially attractive therapeutic target.[13,14] First-generation JAK inhibitors, or jakinibs, inhibit multiple JAKs and thus a large number of cytokines (Table 29-3). Jakinibs are approved for the treatment of rheumatoid arthritis, psoriatic arthritis, juvenile arthritis, and ulcerative colitis and are being investigated for the treatment of a number of other autoimmune and dermatologic conditions.[15,16] Polycythemia vera and related myeloproliferative neoplasms are due to gain-of-function *JAK2* mutations. Ruxolitinib inhibits JAK1 and JAK2 and is approved for the treatment of myeloproliferative neoplasms (Chapter 152) and acute graft-versus-host disease. First-generation jakinibs inhibit JAK2, which mediates signaling of many cytokines, including growth hormone, erythropoietin, thrombopoietin, IL-11, granulocyte colony-stimulating factor (G-CSF), and granulocyte macrophage (GM)-CSF; as a result, treated patients may develop anemia and other cytopenias. Although these effects are not usually severe enough to lead to discontinuation of treatment, newer selective jakinibs are being developed that spare JAK2.

Bruton tyrosine kinase has a critical role in B-cell function.[17] The Bruton tyrosine kinase inhibitors ibrutinib, acalabrutinib, and zanubrutinib are FDA approved to treat chronic lymphocytic leukemia (Chapter 169), Waldenström macroglobulinemia, and lymphoma. In all, more than 35 kinase inhibitors have been approved for multiple indications, including many cancers.

CONCLUSION

The use of biologic agents and signaling inhibitors has led to major improvements in the treatment of a wide variety of diseases, ranging from autoimmunity to malignancies. These targeted therapies have also provided insights into basic pathogenetic mechanisms in many of these disorders. Future directions are likely to focus on improved targeting, with greater selectivity for disease processes while sparing normal pathways, thereby reducing off-target effects. Expansion into other areas of medicine is also likely, with borrowed, modified, or completely new agents.

TABLE 29-3 APPROVED JANUS KINASE INHIBITORS

DRUG	TARGET	INDICATION
Ruxolitinib	JAK1/JAK2	MPN, acute GvHD
Tofacitinib	JAK1/JAK2/JAK3	RA, PsA, UC, polyarticular JIA
Baricitinib	JAK1/JAK2	RA, COVID-19 (EU)
Upadacitinib	JAK1	RA
Filgotinib	JAK1	RA (approved in EU, Japan)
Peficitinib	Multiple JAKs	RA (approved in Japan, Korea)
Fedratinib	JAK2/FLT3/RET/BRD4	MPN

COVID = coronavirus disease; EU = European Union; GvHD = graft versus host disease; JIA = juvenile idiopathic arthritis; MPN = myeloproliferative neoplasms; PsA = psoriatic arthritis; RA = rheumatoid arthritis; UC = ulcerative colitis.

30 COMPLEMENTARY AND INTEGRATIVE MEDICINE

FREDERICK M. HECHT

In addition to the pharmaceutical and surgical therapies that have been central to advances in medical care, a large proportion of people across the globe also use health care treatments that fall outside of conventional medical care. The United States' National Center for Complementary and Integrative Health of the National Institutes of Health has defined complementary health care as "health care approaches developed outside of mainstream Western, or conventional, medicine" when they are used together with conventional medicine, and as alternative medicine when they are used in place of conventional medicine. Integrative medicine is an approach to medical practice that includes conventional medical therapies as well as nonpharmaceutical and nonsurgical therapies that have not always been incorporated or emphasized in conventional medicine but for which some evidence base now exists. This approach typically includes the use of lifestyle, mind-body practices, or natural products. Because these therapies typically receive little or no attention during medical

ABSTRACT

Complementary medicine emphasizes health care approaches outside of mainstream Western or conventional medicine, whether instead of or in addition to conventional medicine. Integrative medicine coordinates complementary and conventional medicine in a unified approach. Each year, over 30% of U.S. adults use complementary medicine therapies, including natural products (e.g., vitamins and mineral supplements, probiotics, and prebiotics) and mind and body practices (e.g., meditation, yoga and tai chi, manual therapies, acupuncture). In the United States natural products are regulated under the Dietary Supplement Health and Education Act, not the Food and Drug Administration (FDA). Increasing evidence is becoming available to guide the use of these complementary therapies.

education and because of conflicting claims and limitations in the quality of existing evidence, counseling patients about these therapies can be challenging.

USE OF INTEGRATIVE AND COMPLEMENTARY TREATMENTS

An estimated one third of Americans over 18 years of age have used some form of integrative health approach in the past 12 months, and the percentage appears to be increasing. The most commonly used practices included natural products, yoga and tai chi, deep breathing, meditation, chiropractic and osteopathic manipulation, and massage. Integrative medicine techniques have also become a common component of pain management in patients with cancer.[1]

MIND AND BODY PRACTICES

MEDITATION

Meditation and related contemplative practices involve various techniques to self-regulate attention. Often derived from different spiritual traditions, meditation has been used for centuries to achieve states of mental and emotional calm, increased awareness of physical sensations and emotional states, and improved attention. More recently, meditation practices are often used in the secular arena, increasingly within health care settings, to help manage stress, improve emotional regulation skills, and address other mental and physical health issues.

Among the different approaches to meditation, the two general types that have received the most study are *mindfulness-based* meditation and *concentration-mantra* meditation. Mindfulness meditation involves practices aimed at "paying attention in a particular way, on purpose, in the present moment, and nonjudgmentally." For example, the Mindfulness-based Stress Reduction program and related programs in health care settings aim to improve the ability of patients to cope with chronic pain. This approach is at least as effective as approaches such as cognitive-behavioral therapy for treating chronic low back pain (Chapter 369), and both approaches are more effective than usual medical care alone.[A1] In patients treated with opiates for chronic pain, mind-body therapies can reduce the intensity of pain and reduce opioid doses, with the largest effect sizes from meditation approaches.[A2]

Another important application of mindfulness-based approaches has been to address mood regulation, particularly in conditions such as depression (Chapter 362). In patients who have experienced at least one prior episode of significant depression, mindfulness-based cognitive therapy, which combines some elements of cognitive-behavioral therapy with mindfulness practices, can reduce relapse rates by about 20% compared with continuing antidepressant medication alone,[A3] without increasing costs. As a result, mindfulness-based cognitive therapy is now recommended as one of the standard-of-care approaches to prevent relapse of depression in the United Kingdom. Mindfulness-based interventions are also increasingly integrated into the workplace in a variety of ways, including web-based programs and classes on yoga or meditation.

A common form of mantra-based meditation is transcendental meditation. A more generic form is mantra meditation, which may evoke a relaxation response. Limited evidence suggests that this approach can lower blood pressure and improve depressive symptoms.

YOGA AND TAI CHI

Although yoga, tai chi, and qigong are practiced for different purposes and with a variety of styles, their goal is to achieve health benefits that go beyond general physical fitness. The focused attention during movement practices can be viewed as a form of moving meditation.

Tai chi can improve balance and reduce the risk of falls by about 50% in the elderly.[A4] In addition, regular tai chi can significantly improve psychological outcomes, including reductions in stress[A5] and depression. Yoga also is effective for low back pain and has been incorporated into guidelines for managing chronic low back pain.[A6] In patients with hypertension, yoga has been reported to decrease systolic blood pressure by up to 10 mm Hg,[A7] although the quality of data is low.

Yoga can be practiced in a variety of ways, and the actual yoga practices are important when suggesting yoga to patients. For example, yoga that is effective for low back pain has been specifically tailored to low back pain—a gentle yoga style to avoid postures that might exacerbate back pain, while focusing on postures and methods that are thought to be useful. Yoga programs designed for conditions such as low back pain are available at some medical centers and yoga studios. If specifically tailored classes are not available, many yoga studios offer restorative yoga classes, which are less likely to include postures and movements that may exacerbate low back pain and are more likely to include a focus on mindful movement and body awareness that may be helpful for low back pain.

MANUAL THERAPIES

Manual therapies include a broad range of physical treatments commonly used by physical therapists, massage therapists, chiropractors, and osteopaths. These therapies typically include massage and manipulation of muscles, as well as techniques to mobilize joints.

Massage therapy is effective for conditions such as neck and shoulder pain,[2] and massage is commonly used for sports injuries, delayed-onset muscle soreness after strenuous exercise, and other causes of muscle pain. The mechanisms though which massage therapy works are not fully understood. However, studies using muscle biopsies after exercise-induced muscle injury have found that massage decreases the production of inflammatory cytokines and increases indicators of cell repair such as mitochondrial biogenesis. Massage therapy has also been shown to reduce anxiety and blood pressure. One important issue for clinicians to understand is the wide range of massage techniques and different types of expertise among massage therapists. Some forms, such as Swedish massage, are aimed largely at relaxation. Other forms of massage, such as sports massage and deep tissue massage, tend to use greater pressure and techniques specifically aimed at enhancing recovery from muscle injury. When referring a patient for massage for issues such as sports injury, it may be helpful to make sure the massage therapist has specific training and experience in working with sports injuries.

Spinal manipulation, which involves applying a controlled force to a joint of the spine, is typically performed by chiropractors or osteopathic physicians but also can be performed by physical therapists and some physicians. Although spinal manipulation has sometimes been viewed with suspicion in conventional medicine, a growing body of evidence supports its use in specific conditions.[3] For example, spinal manipulative therapy is somewhat effective for reducing acute low back pain,[A8,A9] and is now included in the American College of Physicians recommendations for treatment of acute low back pain. Although serious adverse events after spinal manipulation, such as vertebral artery dissection, appear to be very rare, they emphasize the need for skilled practitioners who are properly trained to perform it.[4]

ACUPUNCTURE AND TRADITIONAL CHINESE MEDICINE

Acupuncture,[5] which has been practiced in China for thousands of years, involves placing thin needles in specific sites, or acupuncture points, which are often stimulated in a variety of ways, such as by spinning the needle. Controversy exists as to whether the benefits of acupuncture are due to a placebo effect versus actual effects of the needle insertion. Data from meta-analysis suggest that about 50% of its benefits are consistent with a placebo effect, but it still improves pain compared with sham treatment, such as stimulation of an acupuncture point without a needle penetrating the skin.[A10,A11] Substantial evidence also indicates that acupuncture can decrease the duration of postoperative ileus,[A12] as well as nausea and vomiting after chemotherapy or surgery.[6]

Other components of traditional Chinese medicine include an assessment of potential imbalances or blockages in the circulation of *qi*, or vital energy, through the body; the use of herbal medicine; and recommendations for diet and exercise (including qigong). Evidence for these broader elements of traditional Chinese medicine is still limited. Data are also limited for the true benefit of Ayurveda (traditional medicine from the Indian subcontinent), which includes some elements of yoga along with components parallel to traditional Chinese medicine.

NATURAL PRODUCTS

Natural products encompass vitamins, minerals, herbs (also known as botanicals), and probiotics, all of which are often sold as dietary supplements. Although many of these products have anecdotal support, evidence of efficacy is limited for most of them.[7] Under the 1994 Dietary Supplement Health and Education Act, dietary supplements are considered to be food, so manufacturers are not required to obtain Food and Drug Administration (FDA) approval before marketing any supplement that was already available before 1994 ("grandfathered status"). By comparison, new dietary ingredients introduced after 1994 require reasonable evidence of safety, which must be reviewed before marketing.

Some dietary supplements can cause severe adverse effects, in part due to impurities or excessive levels of certain active ingredients,[8] and in aggregate they represent the second most common cause of drug-induced liver disease (Chapter 136). The Dietary Supplement and Nonprescription Drug Consumer Protection Act of 2006 requires that physicians in hospitals report any serious

adverse event associated with a dietary supplement (using a form available on the FDA website: MedWatch Form 3500 A). The updated status of different natural products is available on the National Center for Complementary and Integrative Health website (https://nccih.nih.gov/health/herbsataglance.htm), and the National Institutes of Health Office of Dietary Supplements has additional information on the current status of different dietary supplements (https://ods.od.nih.gov/factsheets/list-all/).

Although rigorous research has not found evidence that clearly supports the use of many nutritional supplements, intriguing exceptions exist. An example is turmeric (a traditional medicine from the Indian subcontinent), which is high in curcumin, a curcuminoid that has substantial anti-inflammatory and antioxidant properties. Data suggest that a curcuminoid preparation may be more effective than placebo for decreasing pain and improving postexercise recovery.[9]

Potential Interactions with Drug Therapies

One reason for medical providers to be aware of dietary supplements their patients are taking is that some supplements may have potential interactions with other medications. An example is St. John's wort, which may improve depression, although well-designed studies have failed to show that it is more effective than placebo. St. John's wort induces several cytochrome P-450 isoenzymes, and it has significant interactions with a variety of medications that are metabolized through this system, including warfarin, cyclosporine, oral contraceptives, certain antiretrovirals, and selective serotonin reuptake inhibitors. Other herbal supplements with significant potential for drug interactions include goldenseal and ginseng.

VITAMIN AND MINERAL SUPPLEMENTS

Vitamin and mineral supplements are popular and widely used. Observational studies have linked consumption of various micronutrients, or measurements of these micronutrients in blood, to a reduced risk of certain diseases. However, supplementation of vitamins and minerals for the general population has been disappointing, and a number of randomized trials of nutrient supplementation have not only failed to find evidence of benefit but have actually demonstrated harm (Chapter 199).

Together, these considerations suggest that clinicians should focus on having patients follow an overall healthy eating pattern (Chapter 13) that is low in processed foods and high in nutrient-rich foods, rather than relying on dietary supplements. A Mediterranean diet pattern (Fig. 13-1), for example, can reduce cardiovascular risk, and this type of diet should provide adequate micronutrients for most patients. Special conditions in which evidence suggests benefit from micronutrient supplementation include pregnancy (Chapter 221) and conditions such as chronic pancreatitis with pancreatic insufficiency (Chapter 130).

Probiotics and Prebiotics

Growing evidence shows that the human gut microbiome (Chapter 257) has a variety of important influences on health. Probiotics, which are live microorganisms that are thought to be beneficial in the human gut, are available naturally in yogurt and other fermented foods or as dietary supplements. Prebiotics, which are nondigestible food ingredients that promote the growth of beneficial microorganisms, are another potential approach to improving the gut microbiome.

The most impressive evidence for how changing the gut microbiome can treat a medical condition comes from the studies in which fecal transplants from healthy individuals have been used to treat recurrent *Clostridioides difficile*–associated colitis (Chapters 261 and 271).[A13] Probiotics also can reduce the incidence of antibiotic-induced diarrhea.[A14] For irritable bowel syndrome, data have found probiotics may improve global symptoms by about 20%[10] but overall are mixed, and so are the recommendations of professional societies. In trials showing benefit, the most frequently included strains have been *Lactobacillus acidophilus*, followed by *Streptococcus thermophilus*, *Bifidobacterium breve*, and *Bifidobacterium longum*.

OVERVIEW

Although more evidence is needed on many fronts, evidence-based integrative health therapies are increasingly being included in medical practice. When used appropriately, these approaches may expand the tools available to health care practitioners and the options that can be recommended to patients. Many patients may appreciate choices other than drugs in different conditions. For some conditions, such as pain, the use of nonpharmacologic treatments may reduce the risk of harm from conventional treatments, such as overuse of narcotics. Yoga, tai chi, mindfulness-based meditation, self-massage, and acupressure also can be incorporated into telemedicine.[11]

31 PRINCIPLES OF GENETICS

BRUCE R. KORF AND NITA A. LIMDI

The elucidation of the structure and function of the genome is one of the great triumphs of modern science. The relevance of inheritance to health and disease probably has been recognized throughout history, but now the rules governing inheritance and the mechanisms whereby genetic information is stored and used are coming to light. Application of this knowledge to medical practice had long been focused on rare monogenic and chromosomal disorders. Major contributions have been made in these areas in genetic testing, genetic counseling, prenatal diagnosis, newborn screening, carrier screening, and, to an increasing extent, treatment. The era of genomic medicine[1] provides powerful new approaches to the management of both rare and common disorders.

GENETIC ARCHITECTURE OF DISEASE

It may be argued that no disorder is completely determined either by genetic or nongenetic factors. Even monogenic conditions, such as phenylketonuria, are modified by the environment, in this case by dietary intake of phenylalanine. Genetically determined host factors are known to modify susceptibility to infection or other environmental agents. Even individuals who are victims of trauma may find themselves at risk in part because of genetic traits that affect behavior or ability to perceive, escape, or recover from danger.

The number of genetic variants that contribute to a disease phenotype, the degree to which each contributes, and the frequency of these variants in the population is referred to as the genetic architecture of disease (Fig. 31-1).[2] Conditions may be largely determined by a single gene, with other genes playing a smaller role in modifying the phenotype, or may result from the accumulation of small effects of many genes. From a medical perspective, it is helpful to divide the genetic contribution to disease into three categories: (1) high-penetrance monogenic or chromosomal disorders; (2) monogenic versions of common disorders; and (3) complex, multifactorial disorders. Each of these affects medical practice in distinctive ways.

HIGH-PENETRANCE MONOGENIC OR CHROMOSOMAL DISORDERS

High-penetrance monogenic or chromosomal disorders are what most clinicians think of as "genetic conditions." They include rare but familiar single-gene disorders, such as neurofibromatosis, Marfan syndrome, and cystic fibrosis, and chromosomal abnormalities, such as trisomy 21 (Down syndrome). Several thousand distinct human genetic disorders have been described and catalogued in Mendelian Inheritance in Man (available at www.omim.org). These disorders include dominant, recessive, and sex-linked disorders, as well as conditions due to variants within the 16.6-kilobase mitochondrial genome. These disorders also include chromosomal syndromes that are associated with duplication or deletion of small regions of the genome and that may result in specific syndromes, such as Williams syndrome (deletion of contiguous loci from a region of chromosome 7), intellectual disability, or autism spectrum disorder.

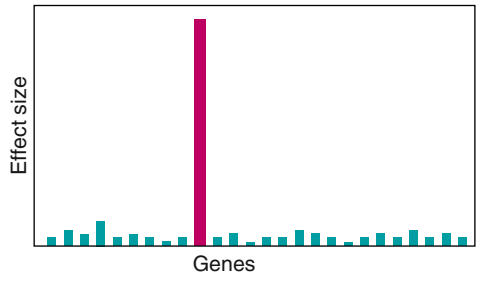

FIGURE 31-1. Diagram illustrating concept of genetic architecture. Different genes are indicated on the x-axis, and their effect size (the degree to which a particular gene contributes to the phenotype) is shown on the y-axis. A disorder associated with variants in a single gene shows a large effect size from that single gene (shown in red). Many other genes (shown in blue) with smaller effect sizes may modify the phenotype, but the major gene is alone sufficient to cause the phenotype.

ROLE OF THE NONSPECIALIST IN MANAGEMENT OF RARE GENETIC DISORDERS

Most clinicians have limited experience with specific rare genetic disorders and are likely to need to refer such patients to a specialist for assistance with diagnosis and management. Nevertheless, the nonspecialist has an important role in the care of these patients. This role begins with realization that the patient may have such a disorder and arrangement for diagnostic evaluation. Many genetic disorders produce obvious signs or symptoms that should prompt referral even if they are not immediately suggestive of a diagnosis. Others can be more subtle, with nevertheless significant consequences if the diagnosis is missed. An example is Marfan syndrome (Chapter 239). The physician needs to be alert to the physical characteristics of patients with Marfan syndrome because life-threatening aortic dissection can be avoided with appropriate monitoring and treatment.

The management of patients with rare genetic disorders may require the assistance of a specialist, but the nonspecialist is likely to be the first contact when an affected individual is ill. The primary care physician should be familiar with the disorder and major potential complications. For example, patients who have neurofibromatosis type 1 (Chapter 385) and who experience chronic back pain require more aggressive evaluation than would be typical for an unaffected individual with back pain because they may be presenting with a malignant peripheral nerve sheath tumor. A good working relationship between the specialist and nonspecialist is crucial to effective care.

The nonspecialist also has an important role in supporting the patient and helping to explain the choices that may be offered for management. This role includes providing support for patients who have disorders that cannot be treated and for the emotional impact that accompanies knowledge that a disorder may be transmitted to one's offspring or shared with other relatives. Most patients have little understanding of the mechanisms of genetics and genetic disease. Although the responsibility to explain these issues may reside with specialists and counselors, the primary care physician has an important supportive role.

GENOMIC APPROACHES TO RARE DISORDERS

Identification of genes that underlie rare disorders enables molecular diagnostic tests to detect pathogenic variants. A database of testing laboratories can be found at www.ncbi.nlm.nih.gov/gtr/. Cytogenomic microarray analysis can reveal small deletions or duplications in individuals with conditions such as autism spectrum disorder, for whom standard chromosomal analysis is unrevealing. Sequencing the entire coding region of the genome (exome sequencing) or the entire genome (genome sequencing) is now being applied clinically.[3] Screening for carrier status for autosomal recessive disorders has been offered for many years, with specific ancestry groups being offered testing for conditions of high prevalence in their group. Genomic approaches are now making it possible to increase the number of conditions tested, thereby enabling a comprehensive screen of dozens or even hundreds of genes regardless of ancestry.[4] Prenatal screening for trisomy and some pathologic copy number changes can be offered noninvasively by analysis of fetal DNA in maternal blood.[5] Newborn screening is being expanded beyond inborn errors of metabolism such as phenylketonuria and galactosemia, with the advent of tandem mass spectrometry and the availability of a standardized panel of tests.[6] Genome sequencing is also effective for identifying genetic disorders in newborns in intensive care nurseries, thereby providing information that can guide management.[7] Genome sequencing has also been evaluated as an approach to newborn screening,[8,A1] though challenges include the inability to detect all pathologic variants associated with treatable newborn diseases, as well as concerns about identification of currently untreatable or later-onset disorders.

Finally, treatment of some monogenic disorders is becoming feasible. Therapies that use either pharmaceuticals or gene or enzyme replacement strategies are in use or being tested for many conditions. The principles of management of genetic disorders are evolving rapidly, and care of patients increasingly requires active partnership among specialists, primary care physicians, and patient advocates. Moreover, individuals with congenital disorders such as Down syndrome are routinely surviving to adulthood and require primary care physicians who are familiar with their special needs.

ABSTRACT

Genetics and genomics are increasingly being incorporated into the day-to-day practice of medicine. Rare diseases have long been the domain of medical genetics, and new techniques of genome sequencing have vastly increased the power of genetic diagnosis. In some cases, targeted therapies are now available or are in development. A proportion of apparently "common disorders" such as cancer and cardiovascular disorders can be attributed to single gene changes as well. Tools are now at hand to identify individuals at risk, in some cases based on genetic testing, but also from analysis of family history. The genetics of multifactorial common disorders are the most difficult to elucidate. Genetic factors associated with risk of common conditions are beginning to be applied clinically in polygenic risk scores. Genetic tests that interrogate variations in drug metabolism can also be used to individualize the selection of medications and their dosing for conditions such as cancer, cardiovascular disease, epilepsy, and psychiatric disorders. As the clinical utility of genomic medicine is gradually established, virtually all areas of medical practice will include genetics and genomics in routine medical decision making.

pharmacogenetics

MONOGENIC VERSIONS OF COMMON DISORDERS

Not all monogenic disorders produce rare phenotypes, and not all common disorders have complex multifactorial causes. Some common disorders occur in families as single-gene traits, mostly with an autosomal dominant inheritance. Age of onset can be variable, and penetrance is usually incomplete (i.e., not all individuals who carry a pathogenic variant become symptomatic). Examples include several cancer predisposition syndromes (e.g., hereditary breast and ovarian cancer, Lynch syndrome, familial adenomatous polyposis, Li-Fraumeni syndrome, and various multiple endocrine neoplasia syndromes), inherited forms of cardiomyopathy, long QT syndrome, and maturity-onset diabetes of the young.[9]

GENETIC TESTING FOR MONOGENIC COMMON DISORDERS

Genetic tests for disorders associated with inherited forms of common disorders are now available, usually as panels that test for variants in multiple genes known to be associated with specific disorders. As with any medical test, the physician must consider the clinical utility of testing before a test is ordered. For example, compelling evidence supports the value of making an early diagnosis of hemochromatosis because the complications can be prevented, but not reversed, by phlebotomy and subsequent monitoring of iron stores. Individuals at risk for colon cancer can be offered surveillance with colonoscopy or surgical resection of the colon to reduce the risk for cancer. Individuals at risk for breast and ovarian cancer likewise can be offered surveillance, chemoprevention, or surgery.

Potential risks of genetic testing, such as guilt or stigmatization, also must be considered. The Genetic Information Nondiscrimination Act of 2008 (GINA)[10] protects individuals in the United States from the use of genetic information as a basis for determining eligibility for employment or health insurance in most instances. Protection does not, however, extend to life insurance or disability insurance. Some states have genetic nondiscrimination laws that exceed the protections of GINA.

ROLE OF THE NONSPECIALIST IN MANAGEMENT

The role of the physician in dealing with monogenic disorders includes recognition of individuals at risk and participation in the creation of a plan of care.[11] The most valuable screening tool is the family history. Directed questioning about a family history of monogenic disorders (especially breast, ovarian, and colon cancer, as well as hypercholesterolemia, hypertension, cardiomyopathy, arrhythmia, deep vein thrombosis, cirrhosis, kidney disease, and diabetes) can help identify the occasional patient with Mendelian segregation of these conditions. Even if the information is of uncertain reliability, eliciting a family history can prompt referral for further evaluation, documentation of the family history, and consideration for genetic testing.

The advent of exome or genome sequencing for diagnosis of rare disorders has opened the possibility of identification of individuals at risk based on secondary findings. The American College of Medical Genetics and Genomics has recommended that testing laboratories evaluate a list of genes for which identification of a pathogenic variant can lead to management to reduce risk, if the patient or parent opts into receiving this information.[12] This information would be shared even if the individual being sequenced is a child, because the condition may have relevance to the eventual health of the child, as well as parents and other relatives.

COMPLEX, MULTIFACTORIAL DISORDERS

Understanding the genetics of common disorders is one of the great challenges of modern medicine, with the promise of major returns in terms of prevention, diagnosis, and treatment. The etiology of these disorders is complex in that they result from an interplay of genes, environment, and individual lifestyles.

GENOME-WIDE ASSOCIATION STUDIES

Dissection of the genetic contribution to common disease cannot be accomplished by study of rare variants or family-based linkage studies. Most efforts have focused on study of large patient cohorts, comparing the association of genetic variants in affected cases as compared with control subjects. The ability to test millions of genetic variants rapidly across the genome has enabled genome-wide association studies (GWAS) to identify variants associated with common disorders. Hundreds of such associations have been found, either because genetic variants themselves contribute to risk or are closely linked with other variants that are involved in the disorder (linkage disequilibrium).

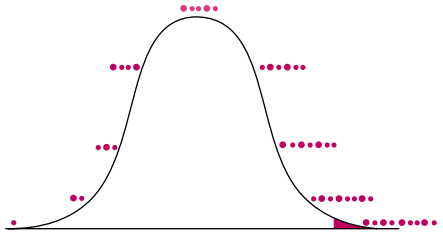

FIGURE 31-2. Concept of polygenic risk score. Individual variants are indicated by red dots, with the effect size depicted by the size of the dot. The phenotype is indicated as showing a normal distribution in the population, with the least affected individuals to the left and the most affected to the right. There is a gradient of numbers of genomic variants along the distribution, with the most severely affected, indicated by the red area under the curve to the right, having the highest polygenic risk score (i.e., the sum of all associated genetic variants weighted by their effect size). In reality, the number of variants incorporated into a polygenic risk score is far larger than shown here.

GENETIC RISK ASSESSMENT

The goal of genetic risk assessment is the identification of individuals at risk for disease before the onset of signs or symptoms. In principle, the genetic factors could be identified at any time in life by testing a DNA sample. Persons found to be at risk can be offered treatment in advance of onset of the disease to avoid complications or might be advised to modify their lifestyle to avoid exposure to dietary or environmental factors that might increase risk of disease.

Polygenic Risk Scores

The contribution to multifactorial disease risk of any one genetic variant is too small to be clinically useful, but risk is additive across multiple variants. Summing the number of risk-associated variants, each weighted by effect size (i.e., the odds ratio of disease in carriers of a specific allele compared with noncarriers) results in a polygenic risk score (Fig. 31-2).[13] Individuals at the upper end of the distribution of a polygenic risk score for a particular trait may have a risk comparable to persons with a single gene Mendelian trait, and they likewise can be offered management to mitigate that risk. Studies are underway to test the clinical utility of polygenic risk scores and determine how they can be integrated into clinical care.[14,15] Specific risk alleles and effect sizes may differ in populations of different ancestry, thereby limiting the portability of polygenic scores across populations. To date most GWAS studies have been performed on populations of European ancestry, so a major effort is required to engage populations historically under-represented in genetics research to enable application of polygenic scores across diverse populations and to avoid exacerbating health disparities.[16]

POPULATION SCREENING

The possibility of early identification of individuals at risk of disease raises the question of the utility of population screening. Some research-based population screening programs have been instituted, based on lists of actionable genomic variants (i.e., variants that are highly predictive of disease for which treatment is beneficial prior to onset of symptoms). The Centers for Disease Control and Prevention have identified a list of "Tier 1 conditions" (specifically hereditary breast and ovarian cancer, Lynch syndrome, and hypercholesterolemia) for which population screening may be beneficial. Low-cost genotyping has also spawned an industry of direct-to-consumer genomic testing for a limited repertoire of tests subject to approval by the Food and Drug Administration.

PHARMACOGENETIC TESTING

Response to medications, the principal treatment modality for acute and chronic diseases, is highly variable, ranging from inadequate efficacy to adverse drug reactions. Variations in genes associated with drug pharmacodynamics and pharmacokinetics (absorption, distribution, metabolism, and excretion) has a significant effect on response and dose requirements (Table 31-1). The Clinical Pharmacogenetic Implementation Consortium (https://cpicpgx.org/guidelines/) and the Food and Drug Administration (https://www.fda.gov/medical-devices/precision-medicine/table-pharmacogenetic-associations) provide clinical guidance on the use of genotypic information to optimize medication regimens. With approximately 15 to 30% of response variability explained by genetic variants, pharmacogenetics has become a valuable tool for optimizing the selection and dosing of medications, and it is poised to

TABLE 31-1 GENES IN WHICH COMMON POLYMORPHISMS AFFECT RATES OF DRUG METABOLISM OR ACTION

GENE	EXAMPLES OF AFFECTED DRUG(S)

32 CLINICAL GENOMICS—GENOME STRUCTURE AND VARIATION

LESLIE G. BIESECKER

CLINICAL GENOMICS

Genomics is a biomedical discipline that addresses the structure, function, evolution, mapping, and editing of all of the DNA of an organism. Genomics also encompasses a broad and rapidly changing suite of technologies that use 1 high-throughput assays to assess the molecular basis of heritable disease.[1]

The growth of genomic medicine is exemplified by the more than 3 million individuals who already have been evaluated using genome sequencing and many others using exome sequencing. At least 1 of every 25 of patients has a mendelian genetic disorder, and many more have polygenic disorders. This simple arithmetic indicates that practicing clinicians are likely to have sequenced patients in their practices and must learn to recognize and manage individuals with inherited diseases.

A genome is the nuclear DNA included in 23 pairs of chromosomes: 22 autosomes plus two sex chromosomes (XX in females and XY in males). The diploid genome (2n) comprises two haploid copies, each of about 3 billion base pairs (bp). Two haploid genomes are reconstituted in the fertilized embryo as a diploid genome, for a total of 6 billion nucleotides. The protein coding genetic sequences include about 23,000 genes and comprise a minority (about 2%) of the human genome. The many other biologically relevant sequences include noncoding RNAs and conserved regulatory elements. In spite of this biologic complexity, clinicians can focus on the 2% of the genome that encode genes, because those genes harbor the variations that are currently best understood as being important for diagnosing and managing patients.

GENE

Genes, which are the units of heredity, are the biologic basic of the transmission of genetic traits and diseases. Genes comprise segments of DNA that encode the information carried by the gene. Precisely mapping the gene onto the nucleotides of the genome can be challenging, because it can be difficult to appreciate all of the disparate DNA elements, such as enhancers and promoters, that contribute to gene regulation and function.

Genomic DNA is configured in a two-stranded, double-helical macromolecule. A DNA strand comprises millions of one of four nucleotides: two purine bases, adenine (A) and guanine (G), and two pyrimidine bases, thymine (T) and cytosine (C). Two such strands, in opposite orientation and with an elegant twist, compose the double helix. Three consecutive nucleotides (triplet codon) of coding DNA specify an amino acid. The 64 possible different codons code for only 20 amino acids, so more than one codon triplet can code for a single amino acid. The information that codes for proteins in most protein-coding genes is broken up into several segments, referred to as exons, which are separated by noncoding introns (Fig. 32-1). The entire gene (exons and introns) is transcribed into messenger RNA (mRNA) by RNA polymerase. In the subsequent splicing process, the intervening introns are deleted; then the spliced, mature mRNA is translated into a polypeptide. At the end of the open reading frame of the gene, the polypeptides are terminated by one of three termination codons.

PATTERNS OF INHERITANCE

MENDELIAN INHERITANCE

Many heritable traits in humans can be attributed to variation of a single gene (monogenic) and segregate in a mendelian inheritance pattern[2]: autosomal 2 dominant, autosomal recessive, or sex-linked. An understanding of inheritance begins with understanding the genotype, which is the status (normal or variant) of a given pair of alleles of genes in an individual. For females, inheritance is straightforward because they have 23 pairs of homologous chromosomes (22 pairs of autosomes and one pair of X chromosomes), whereas males have 22 pairs of autosomes, but only one X and one Y chromosome. Thus, in females, the status of all genes is either homozygous normal (both normal), homozygous variant (both variant), heterozygous (one of each), or compound heterozygous (two different, but both variant). By comparison, genes on the X chromosome of males can be either hemizygous normal or hemizygous variant, to denote the fact that they only have one X chromosome. Only a few genes have alleles on the X and the Y chromosome.

Autosomal dominant inheritance is the pattern that results from a disorder in which the gene is located on an autosome (i.e., not a sex chromosome) and harbors just one copy of an abnormal allele (heterozygote) that is sufficient to cause the phenotype (Fig. 32-2A). The phenotype of an individual who harbors two identical abnormal alleles (homozygote) or two different abnormal alleles (compound heterozygote) is also abnormal. The heterozygous genotype is much more common than the homozygous or compound heterozygous genotype. If a parent is heterozygous, the variant is present in only one of their two alleles, and there is a 50% chance of transmission to each offspring. In pedigree analysis, autosomal dominant inheritance is recognized as a vertical transmission of the trait—from parent to child. However, there is a nuance in dominant inheritance. A trait is formally called autosomal dominant only when the phenotype of the heterozygote is the same as the homozygous variant (see Fig. 32-2A). In reality, this relationship is true for very few human disorders, Huntington

32 CLINICAL GENOMICS—GENOME STRUCTURE AND VARIATION

LESLIE G. BIESECKER

CLINICAL GENOMICS

Genomics is a biomedical discipline that addresses the structure, function, evolution, mapping, and editing of all of the DNA of an organism. Genomics also encompasses a broad and rapidly changing suite of technologies that use 1 high-throughput assays to assess the molecular basis of heritable disease.[1]

The growth of genomic medicine is exemplified by the more than 3 million individuals who already have been evaluated using genome sequencing and many others using exome sequencing. At least 1 of every 25 of patients has a mendelian genetic disorder, and many more have polygenic disorders. This simple arithmetic indicates that practicing clinicians are likely to have sequenced patients in their practices and must learn to recognize and manage individuals with inherited diseases.

A genome is the nuclear DNA included in 23 pairs of chromosomes: 22 autosomes plus two sex chromosomes (XX in females and XY in males). The diploid genome (2n) comprises two haploid copies, each of about 3 billion base pairs (bp). Two haploid genomes are reconstituted in the fertilized embryo as a diploid genome, for a total of 6 billion nucleotides. The protein coding genetic sequences include about 23,000 genes and comprise a minority (about 2%) of the human genome. The many other biologically relevant sequences include noncoding RNAs and conserved regulatory elements. In spite of this biologic complexity, clinicians can focus on the 2% of the genome that encode genes, because those genes harbor the variations that are currently best understood as being important for diagnosing and managing patients.

GENE

Genes, which are the units of heredity, are the biologic basic of the transmission of genetic traits and diseases. Genes comprise segments of DNA that encode the information carried by the gene. Precisely mapping the gene onto the nucleotides of the genome can be challenging, because it can be difficult to appreciate all of the disparate DNA elements, such as enhancers and promoters, that contribute to gene regulation and function.

Genomic DNA is configured in a two-stranded, double-helical macromolecule. A DNA strand comprises millions of one of four nucleotides: two purine bases, adenine (A) and guanine (G), and two pyrimidine bases, thymine (T) and cytosine (C). Two such strands, in opposite orientation and with an elegant twist, compose the double helix. Three consecutive nucleotides (triplet codon) of coding DNA specify an amino acid. The 64 possible different codons code for only 20 amino acids, so more than one codon triplet can code for a single amino acid. The information that codes for proteins in most protein-coding genes is broken up into several segments, referred to as exons, which are separated by noncoding introns (Fig. 32-1). The entire gene (exons and introns) is transcribed into messenger RNA (mRNA) by RNA polymerase. In the subsequent splicing process, the intervening introns are deleted; then the spliced, mature mRNA is translated into a polypeptide. At the end of the open reading frame of the gene, the polypeptides are terminated by one of three termination codons.

PATTERNS OF INHERITANCE

MENDELIAN INHERITANCE

Many heritable traits in humans can be attributed to variation of a single gene (monogenic) and segregate in a mendelian inheritance pattern[2]: autosomal 2 dominant, autosomal recessive, or sex-linked. An understanding of inheritance begins with understanding the genotype, which is the status (normal or variant) of a given pair of alleles of genes in an individual. For females, inheritance is straightforward because they have 23 pairs of homologous chromosomes (22 pairs of autosomes and one pair of X chromosomes), whereas males have 22 pairs of autosomes, but only one X and one Y chromosome. Thus, in females, the status of all genes is either homozygous normal (both normal), homozygous variant (both variant), heterozygous (one of each), or compound heterozygous (two different, but both variant). By comparison, genes on the X chromosome of males can be either hemizygous normal or hemizygous variant, to denote the fact that they only have one X chromosome. Only a few genes have alleles on the X and the Y chromosome.

Autosomal dominant inheritance is the pattern that results from a disorder in which the gene is located on an autosome (i.e., not a sex chromosome) and harbors just one copy of an abnormal allele (heterozygote) that is sufficient to cause the phenotype (Fig. 32-2A). The phenotype of an individual who harbors two identical abnormal alleles (homozygote) or two different abnormal alleles (compound heterozygote) is also abnormal. The heterozygous genotype is much more common than the homozygous or compound heterozygous genotype. If a parent is heterozygous, the variant is present in only one of their two alleles, and there is a 50% chance of transmission to each offspring. In pedigree analysis, autosomal dominant inheritance is recognized as a vertical transmission of the trait—from parent to child. However, there is a nuance in dominant inheritance. A trait is formally called autosomal dominant only when the phenotype of the heterozygote is the same as the homozygous variant (see Fig. 32-2A). In reality, this relationship is true for very few human disorders, Huntington

ABSTRACT

Human genomics is a biomedical discipline that addresses the structure, function, evolution, mapping, and editing of all of the DNA of a patient by using high-throughput assays to assess the molecular basis of heritable disease. Genomics is changing the practice of medicine today, and all clinicians are likely to have patients with genetic diseases in their practice. Clinicians must know the fundamentals of gene and genome structure, as well as the myriad types of genomic variation and how those variations are correlated with inherited patterns of disease. Such knowledge can guide the ordering of genetic testing and the understanding of its results.

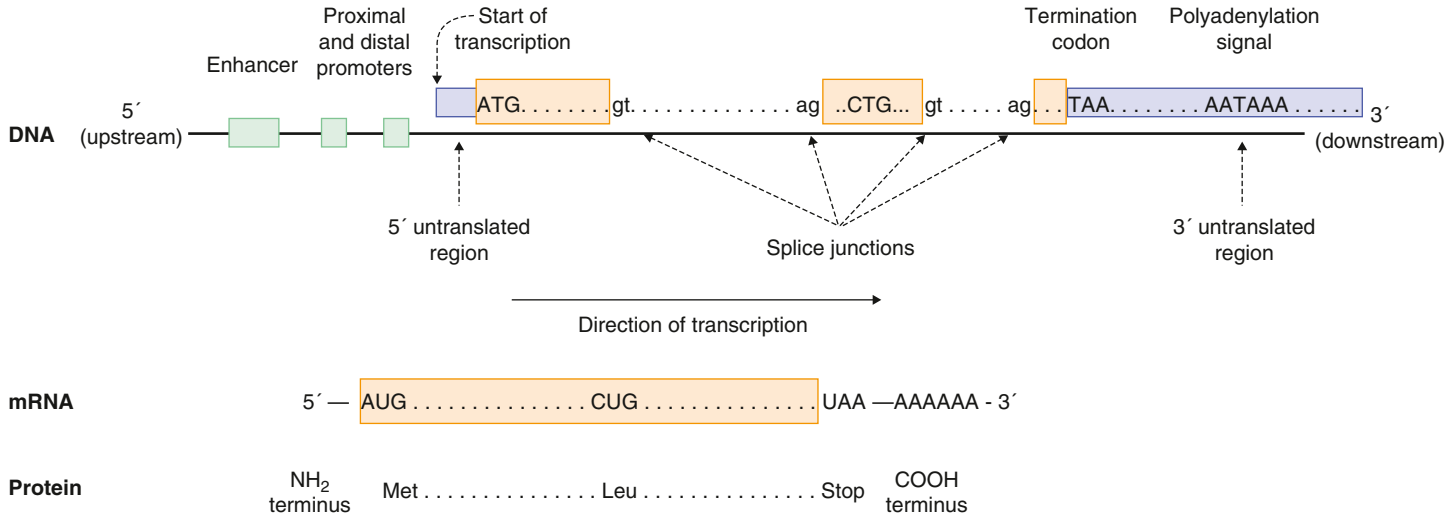

FIGURE 32-1. Gene structure. Illustration of the general structure of a gene. Three exons are depicted as rectangles, comprising sequences that code for proteins *(orange)* or are noncoding *(blue)*. Note that the translation typically starts with an ATG triplet, which encodes the amino acid methionine. The upstream portion of a gene corresponds to the NH_2 terminus, and the downstream portion encodes the COOH terminus of the encoded protein. Enhancers and promoters are shown as *green* rectangles. A = adenine; C = cytosine; G = guanine; T = thymine; u = uracil.

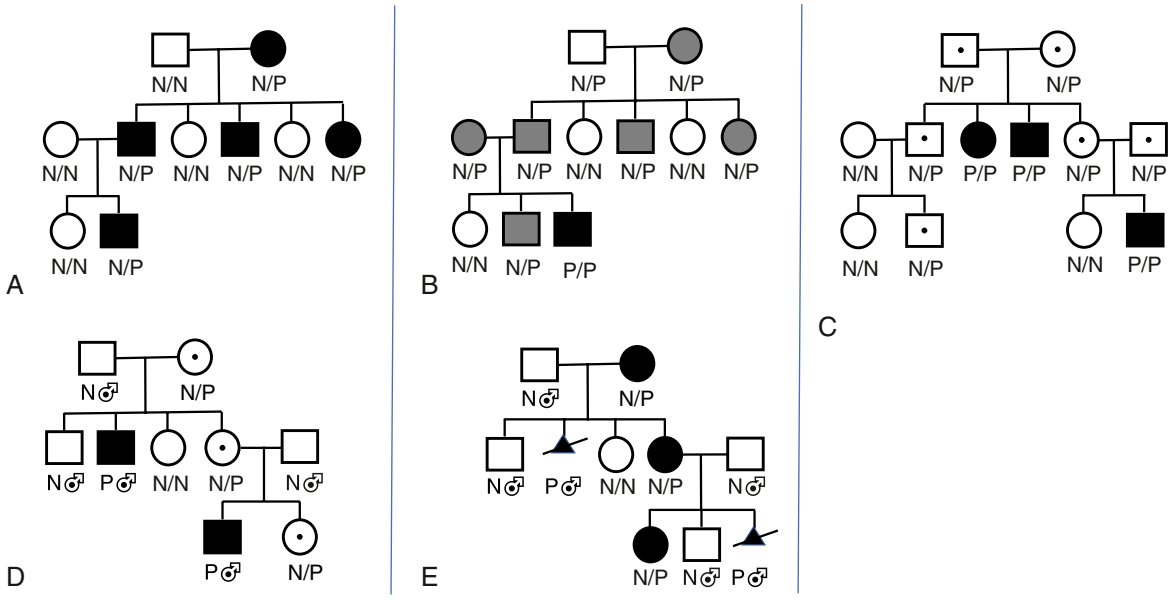

FIGURE 32-2. Modes of inheritance. In the classic mendelian modes of inheritance, the inheritance pattern that is observed in families is determined by the biologic effects of the variants in the gene. In autosomal dominant inheritance (**A**), the pattern reflects the fact that the abnormal variant allele causes a phenotype when only one copy is present and it overrides the normal allele. Two copies of the variant can cause the same severity as one, or it may be more severe (see **B**). In semidominant inheritance (**B**), the effects of the abnormal variants are additive—so two copies of the variant are more severe than one. In autosomal recessive inheritance, (**C**) one copy of the abnormal variant causes little or no abnormality, and so only individuals with two variant alleles have the disorder. The sex-linked inheritance patterns (**D, E**) parallel the same ideas as for the autosomal patterns, with the caveat that males only have one copy of the gene, and thus have fewer combinations of alleles. Squares = male; circles = female; black symbols = affected individuals; symbols with a dot in center = carriers; white symbols = unaffected individuals; gray symbols = individuals affected with phenotype of intermediate severity; black triangle crossed out = terminated pregnancy.

disease being one. For most disorders that are described as having autosomal dominant inheritance, the phenotype of the heterozygote is intermediate in severity between that of the two homozygous states (normal and variant) (see Fig. 32-2B). The classic example is familial hypercholesterolemia, in which the heterozygote phenotype has moderate hypercholesterolemia (low-density cholesterol levels of 190 to 500 mg/dL), whereas the homozygous (or compound heterozygous) variant phenotype is much more severe (levels >500 mg/dL). The formal term for this characteristic is semidominant (or incompletely dominant) inheritance. In humans, most pathogenic variants of this type are sufficiently rare that there are very few matings in which both parents are heterozygous for pathogenic variants in the same gene, so homozygosity is not commonly observed in their offspring. In common usage, all human traits that follow either the "true" autosomal dominant or the semidominant patterns are called autosomal dominant. One final type of dominant inheritance is codominant, best known as the inheritance pattern of the ABO blood type system, in which both alleles are expressed independently, and neither dominates the other.

Autosomal recessive inheritance is the pattern that results from variants in which the phenotype of the heterozygote (termed a "carrier") is unaffected (Fig. 32-2C). This characteristic is the main distinction between autosomal recessive inheritance as compared with autosomal dominant inheritance. In autosomal recessive inheritance, the affected individuals have two pathogenic variants at a single locus, one on each chromosome. These variants can either be the same (homozygous) or distinct (compound heterozygous). Typically, both pathogenic variants are inherited, one each, from an unaffected carrier parent. Because there is a 1 in 2 chance of transmission of the pathogenic variant from each parent, there is a 1 in 4 chance that an offspring will inherit the pathogenic variants from both parents (½×½). Autosomal recessive inheritance is observed as horizontal occurrence of the trait—that is, multiple affected siblings, but no parent-to-child transmission because the carrier parents are unaffected. Occasionally heterozygotes may manifest a mild phenotype, which is indeed the same situation described above for what was termed semidominant inheritance. However, if the heterozygous phenotype is very mild

or only detectable with sophisticated and sensitive phenotyping, the trait is considered to have an autosomal recessive inheritance pattern.

In sex-linked inheritance, the gene is on the X chromosome (it is sometimes called X-linked inheritance). Father-to-son transmission is not observed because if a father is affected, he harbors the pathogenic variant on his sole X chromosome; he can either transmit his X chromosome with the pathogenic variant (in which case the offspring must be female) or he can transmit his Y chromosome, which cannot have the pathogenic variant (in which case the offspring is male). Males only have one X chromosome, so when they harbor an abnormal allele, their genotype is said to be hemizygous. All daughters of affected fathers are therefore heterozygotes for the pathogenic variant. The clinical manifestations of sex-linked inherited disorders is complicated by X-inactivation. This X-inactivation process provides a degree of similarity in gene expression between the sexes—males only have one X chromosome, so gene dosage is 1.0. The X-inactivation process balances expression between males and females by randomly silencing the expression of most genes on X on one of the two chromosomes in females, leading to a functional gene dosage of 1.0.

Taking X-inactivation into account and the various combinations of genotype and phenotype that can manifest in sex-linked disorders, there are two classic patterns. The sex-linked recessive inheritance pattern (see Fig. 32-2D) is typically associated with a partial loss of function allele, which reduces, but does not abrogate gene function and is not cell-lethal. This inheritance pattern typically only manifests in affected males. Female heterozygotes, having one normal allele of the gene, are unaffected because 50% dosage is sufficient for normal function. This principle assumes random X-chromosome inactivation. However, females with incomplete X-inactivation can manifest the phenotype of what is typically a sex-linked recessive inheritance pattern disorder. In sex-linked recessive inheritance, heterozygous (carrier) females have a 1 in 2 probability that each male offspring is affected and a 1 in 2 probability that each female offspring is a heterozygous carrier. If the disorder is such that affected males can reproduce, all of their male offspring are unaffected, and all their female offspring are heterozygous carriers. The classic description of sex-linked dominant inheritance (see Fig. 32-2E) is typically associated with more severe alleles, which are cell-lethal. This lethality leads to nonviability of the male embryos, so the pathogenic variant is not observed in males. Female heterozygotes are affected and have a 1 in 2 chance that each female offspring will also be affected; there is also a 1 in 2 chance a male will receive the variant, but all affected males die early in development.

Formally, the terms autosomal dominant, autosomal recessive, and sex-linked describe inheritance patterns, not genes, diseases, alleles, or variants. Although this distinction may seem arcane, it is important because the inheritance pattern descriptor can be confused with the descriptor for the cellular basis of the disease. This is most obvious for cancer susceptibility traits caused by variants in tumor suppressor genes (see Chapter 166). The inheritance pattern of the clinical trait, which is increased susceptibility to cancer, is autosomal dominant. Biologically, however, such disorders are often described as cellular recessives, because the phenotype of cancer only manifests following a secondary, somatic variant in the gene, thereby causing the cells to be homozygous or compound heterozygous for variants in the gene. As well, it is best to associate disease or abnormal phenotypes to pathogenic variants in the gene, not to the gene itself. In this respect, one should describe a patient as "having a pathogenic variant in a Lynch syndrome gene," instead of saying the person "has the Lynch syndrome gene." It is also nonsensical to say that a patient "has the Lynch syndrome gene" because in fact essentially all humans have two copies of such genes. As well, it is incorrect to say that colon cancer is "caused by the Lynch syndrome gene." Genes do not cause disease—they "cause" normal and abnormal physiology.

NONMENDELIAN INHERITANCE

Genetic disorders can present with multiple occurrences in a family (multiplex) or as a single occurrence (simplex). Simplex occurrence of disease can be explained by a classic mendelian autosomal recessive, X-linked recessive, or autosomal dominant inheritance pattern. For the autosomal recessive pattern, it may be simply by chance in the family; for the X-linked recessive pattern, it may have been inherited silently through females in prior generations; and in either, it may develop through a de novo (new) mutation. However, simplex occurrence disease also might be due to nonmendelian inheritance such as genomic imprinting, uniparental disomy, digenic inheritance, mosaicism, and mitochondrial DNA variants. For these reasons, the clinician should be alert for families in which only a single individual is apparently affected. Other atypical modes of inheritance not further considered here include mitochondrial inheritance, imprinting, digenic inheritance, and uniparental disomy.

Mosaicism

An important exception to mendelian inheritance is the concept of mosaicism.[3] 3 Mosaicism is defined as the presence of two or more cell lines that originated from the same zygote but have distinct chromosomal or gene variant complements. A chimera is when the cells originated from different zygotes, as is the case in an individual who receives transplanted tissue. Some mosaic disorders can manifest patchy pigmentary abnormalities that follow the lines of Blaschko. Mosaicism is common in a number of well-recognized disorders, such as seborrheic keratoses of the skin, which are caused by somatic variants in *PIK3CA* or *FGFR3,* and paroxysmal nocturnal hemoglobinuria, which is associated with somatic variants in *PIGA*. Mosaicism is also the genomic basis of cancer—a clone of cells with extensive variants that originated from a normal cell in an individual (see Chapter 166). Mosaicism can also arise in the hematopoietic lineage with age. This phenomenon has become important in internal medicine in the phenomenon of clonal hematopoiesis of indeterminant potential (CHIP). This condition causes an elevated risk of myelodysplastic conditions, vascular disease, and other disorders, most commonly in older individuals.[4,5] 4 5

Mosaicism can also affect the risk of recurrence for genetic diseases. A parent can harbor two or more cell lines in the gonads (germline mosaicism) or in somatic cells. The level of mosaicism in the somatic cells may be low enough or limited to non-critical tissues or organs such that the parent appears unaffected, or they may be affected in a patchy pattern (Fig. 32-3). Mosaicism should be suspected when two or more children of healthy parents develop a disease that is typically inherited in an autosomal dominant pattern.

GENOMIC VARIATION IN HUMANS

Variation in the genome is the fundamental biologic basis of all heritable traits and diseases.[6] This spectrum of genomic variation runs the gamut from one base 6 pair (a single nucleotide variant [SNV]) to 3×10^9 base pairs (triploidy, which is three copies of a genome, rather than the normal two), and everything in between. The categories of genomic variation that are described later represent slices of that spectrum of variation, and are handy categorical clusters of this variation (much as red, orange, yellow, green, cyan, blue, and violet are useful but arbitrary slices of the continuous, visible electromagnetic spectrum). Another dimension of the broad and continuous spectrum of genomic variation is the relationship of this variation to health and disease. A given single nucleotide variant can be so devastating that it is 100% lethal early in embryonic development. On the other extreme, each of us has over a million single nucleotide variants that have no known biologic consequences.

MUTATION AND VARIANTS

The process of changing a genome from one state to another is termed a mutation. Mutation is a process, not a state. Mutation is defined as the process of a change in nucleotide sequence owing to errors of DNA replication, recombination, or repair, radiation, chemical mutagens, or transposons. A variant is a state of the genome such that one or more nucleotides differ from the reference sequence. At first this may seem arbitrary and unsatisfying—it seems to be dodging the issue of whether a variant is normal or abnormal, disease-associated, or benign. But there is utility and merit to this approach because it is not so simple that at a given position an adenine is normal whereas a cytosine, guanine, or thymine is abnormal. Genetic variation can be complex and subtle, so the new formulation is simply to define a reference sequence, but not necessarily call it normal or abnormal. Because the reference is based on sequences from actual human beings, it is a mix of both. Then a variant is simply described as being different from, or the same as, the reference. Genomic variants can be inherited from a parent (hereditary, constitutional, or germline variants; see Fig. 32-2A–D) and thus be present in every cell, or variants can be acquired in only some tissues during development or any time during life (somatic or mosaic variants) (see Fig. 32-3).

SINGLE NUCLEOTIDE VARIANTS AND OTHER SMALL VARIANTS

Single nucleotide variants are defined as a change of one nucleotide at a given position. Nonsynonymous variants are gene changes that can either lead to a single amino acid change (missense); alter the reading frame and thereby lead to alteration in the downstream protein structure (frameshift) or introduce a stop codon (premature termination codon) that truncates the protein prematurely (nonsense); or abolish the specific site at which splicing of an intron takes place during the processing of precursor mRNA into mature mRNA (splice site). Most mRNAs with nonsense variants are inactivated and

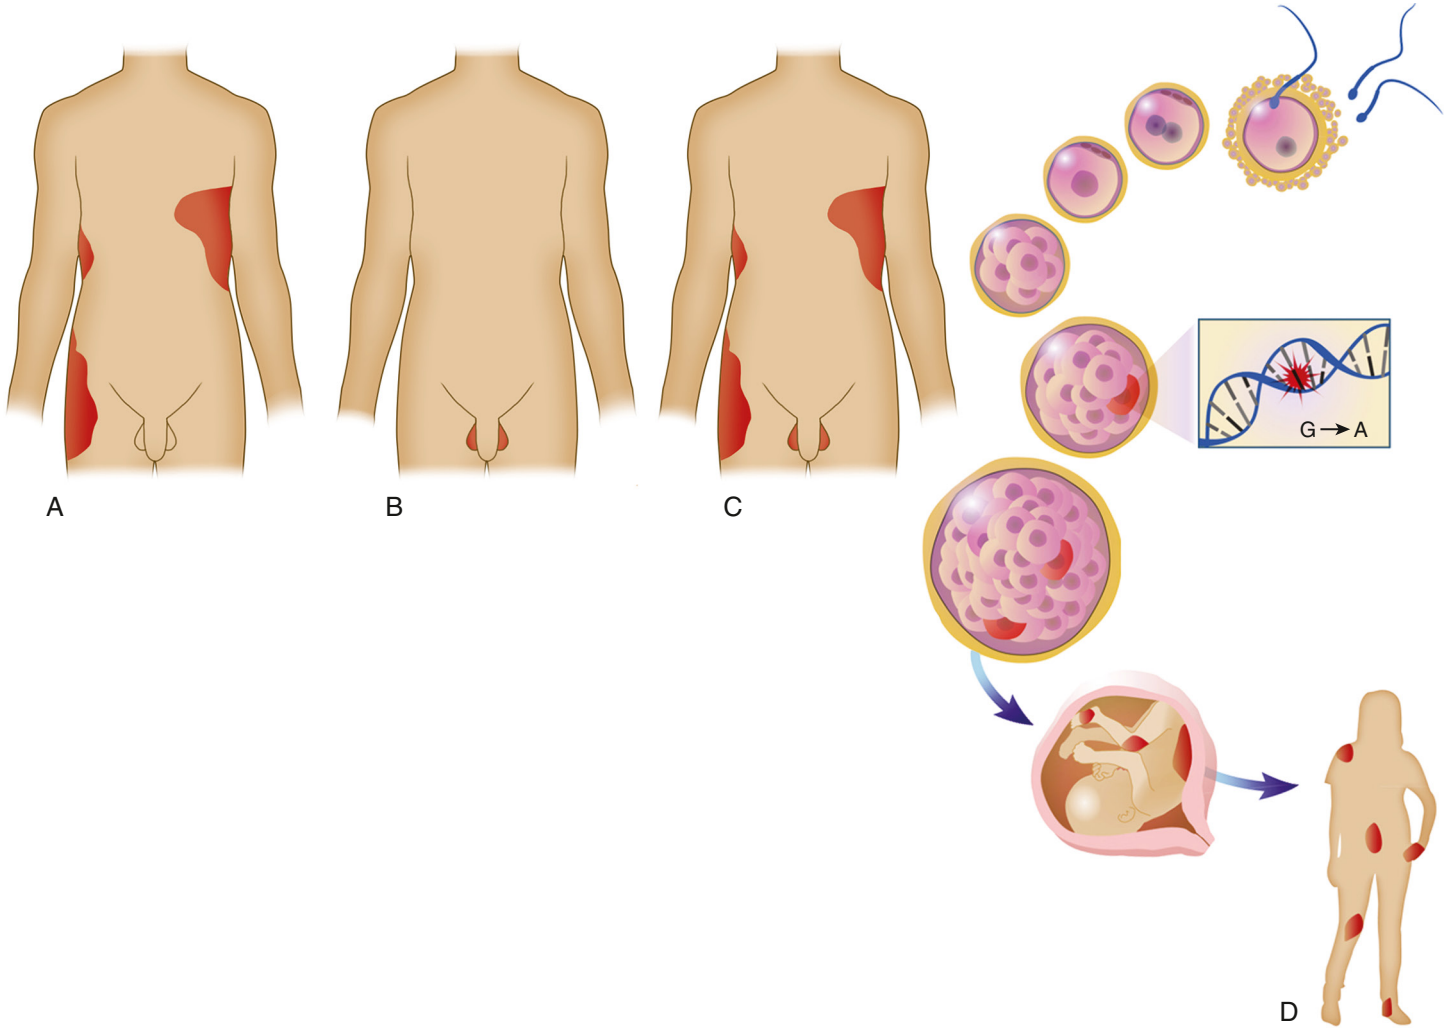

FIGURE 32-3. Types of mosaicism. Mosaicism is categorized into germline and somatic. A given individual can harbor a mosaic variant in one of two general categories of cells: germline or nongermline (somatic) cells. Thus, an individual can harbor in either (**A** or **B**) or both (**C**) of these compartments. How mosaicism is generated is illustrated in **D**. After fertilization, in a multicellular embryo, one cell undergoes a mutation and all of the cells that derive from that cell harbor the variant. (From Spinner N, Biesecker LG. Mosaicism in human disease. *Nat Rev Genet*. 2013;14:307-320.)

removed from cells by a surveillance mechanism called nonsense mediated decay. The most common mutation, cytosine to thymine, is about 10-fold more common than other base changes and occurs in the methylated CpG dinucleotide (a cytosine-guanine sequence) because methylated cytosine can be deaminated and converted to thymine.

Any two unrelated humans differ on average by about 3.5 million single nucleotide variants (≈0.1% of the 3 billion bp reference haploid genome). Whereas most of these single nucleotide variants lie outside of the exons, on average about 20,000 single nucleotide variants occur in coding regions; among these variants, about 7000 to 10,000 are nonsynonymous (i.e., change the encoded amino acid). Single nucleotide variants located outside of the protein-coding regions can still have phenotypic effects, such as by modifying gene regulatory elements, altering the binding sites for transcription factors, generating splicing variants, or affecting noncoding RNAs. The former term, single nucleotide polymorphism (SNP), was initially defined as a DNA variation that is present in greater than 1% of the population, but this term is now discouraged because "polymorphism" carried with it connotations of being "benign," which is clearly false for a substantial number of single nucleotide polymorphisms.

Variants are divided into substitutions, insertions, and deletions. Variants in protein-coding sequence that change the protein structure are termed nonsynonymous, whereas those that do not lead to protein changes are termed synonymous. Synonymous variants can still have functional consequences, such as by generating a new (abnormal) splice site or an exon splice enhancer, or by affecting regulatory elements. A set of consecutive single nucleotide variants (or other variants) that lie on a single chromosome is defined as a haplotype. A nonrandom association of markers in a population not interrupted by meiotic recombination (crossing over) is described as linkage disequilibrium. More than 100,000 single nucleotide variants have been shown to cause mendelian disorders. Many of these disorders are cataloged in locus-specific databases (http://www.hgvs.org/locus-specific-mutation-databases), the Human Gene Mutation Database (http://www.hgmd.cf.ac.uk/ac/index.php), and ClinVar (https://www.ncbi.nlm.nih.gov/clinvar/).

DELETIONS, INSERTIONS, AND INDELS

These variations are less common than single nucleotide variants. They comprise small nucleotide alterations, including deletions of one to a moderate number of nucleotides, insertions of one or a moderate number of nucleotides (which may be a duplication of adjacent DNA or nucleotides from elsewhere in the genome), and variants that comprise both a deletion of one or more nucleotides and an insertion of one or more nucleotides. Many of these variants are cataloged in the same databases as described earlier for single nucleotide variants.

TANDEM REPEATS

The genome contains a large number of repetitive elements, the most clinically important of which are the short tandem repeats (e.g., dinucleotides, trinucleotides, and tetranucleotides—$[GT]_n$, $[CAA]_n$, or $GATA]_n$—called microsatellites). These highly polymorphic repeats can have a wide range of copy numbers of their repeating subunits.[7] A number of these markers can be used to derive a nearly unique pattern of genotypes for each individual, as is used in identification for criminal forensic and paternity analysis (https://www.fbi.gov/services/laboratory/biometric-analysis/codis).

The instability of these repeats leads them to be unstable (dynamic) within individuals; humans can be complex mosaics of a range of repeat lengths among their cells. Pathogenic dynamic expansion of trinucleotide, tetranucleotide, and

pentanucleotide repeat sequences can cause disease whether located in coding regions (e.g., $[CAG]_n$ triplet in *HTT*-related Huntington disease), noncoding introns (e.g., $[GAA]_n$ in *FXN*-related Friedreich ataxia), in the upstream noncoding part of the gene (e.g., $[CGG]_n$ in *FMR1*-related fragile X syndrome), or in the downstream noncoding part of the gene (e.g., $[CTG]_n$ in myotonic dystrophy) regions. These variants can cause disease in an autosomal dominant pattern (e.g., *DMPK*-related myotonic dystrophy), autosomal recessive pattern (e.g., *FXN*-related Friedreich ataxia), or sex-linked pattern (e.g., *FMR1*-related fragile X syndrome) owing to a gain or loss of function of the encoded protein that is altered by the repeat mutation. For each of the unstable repeat diseases, a repeat number threshold exists, above which the disease is manifested. The number of repeats below that threshold but greater than normal is referred to as a pre-mutation. However, in some of these genes, pre-mutations are also associated with a milder, later onset, and sometimes distinct phenotype (e.g., ovarian failure in females and late-onset neurologic disorders in males with premutations in the *FMR1*-related fragile X syndrome). The number of repeats tends to expand in subsequent generations—a phenomenon called anticipation, which typically occurs in a sex-specific manner.

STRUCTURAL VARIANTS AND COPY NUMBER VARIANTS

It has long been recognized that genomes can have large-scale variation in the amount of DNA or the arrangement of DNA, as delineated by microscopic chromosomal analysis. Recent technologic advances (Chapter 33) have improved the ability to identify and characterize these variations. High-resolution analysis of human genome sequences has identified both moderate scale and higher order architectural features, with a potential to cause genomic instability and extensive submicroscopic structural variations. Copy number variant is the term used to describe a larger scale gain or loss of DNA from a chromosome, as compared to an insertion, deletion, or indel, as described above. Again, all of these categories are arbitrarily defined, and some of these categories more reflect how they are detected rather than a biologically based categorization. On average, each individual harbors about 1000 copy number variants, with sizes ranging from 500 bp to 1.2 Mb (million base pairs). These structural variations consist of copy number gains or losses, including deletions, insertions, duplications, and triplications, as well as balanced rearrangements such as genomic inversions and balanced translocations. The frequency of smaller copy number variants (<1 kb, kilobase pair) and indels (insertion or deletion of bases <100 bp) is higher than the larger rearrangements, because they are biologically better tolerated. The number of copy number variants is far smaller than the number of single nucleotide variants, but if one counts the base pairs that are abnormal, more base pairs are in copy number variants than in single nucleotide variants in any given individual.

Copy number variants are associated with mendelian diseases, nonmendelian traits (e.g., complex diseases), and common traits (including neurobehavioral traits),[8] but they also can be benign. Copy number variants can cause disorders by disrupting the gene structure or by changing the copy number of dosage-sensitive genes. However, copy number variants that involve nongenic sequences and leave a gene intact also can have long-range effects by changing the expression of neighboring genes. The Toronto Database of Genomic Variants (http://projects.tcag.ca/variation) summarizes copy number variants, and many clinically relevant copy number variants are also included in the Database of Chromosomal Imbalance and Phenotype in Humans using Ensembl Resources (DECIPHER) (https://www.deciphergenomics.org/).

CHROMOSOMAL ABERRATIONS

Chromosomal aberrations are the class of genomic variation that causes the greatest perturbation of DNA. Chromosomal aberrations, which can be divided into numerical and structural aberrations, occur in about 1 in 160 live births. Although many of the associated phenotypes are rare, the general clinician is likely to have individuals with the more common disorders in their practice.

Most numerical chromosome aberrations result in prenatal lethality. Numerical aberrations are classified as either polyploidy (number of chromosomes are in multiples of the haploid set of 23 chromosomes) or aneuploidy (with extra or missing chromosomes not in multiples of the haploid set). A normal female chromosome complement is 46,XX and male is 46,XY. Polyploidies such as triploidies (69,XXX, 69,XXY, and 69,XYY) are caused by abnormal fertilization of the egg by two sperms, whereas tetraploidies (92,XXYY or 92,XXXX) are caused by a failure in zygote division. Among *viable* chromosomal aneuploidies, the most common trisomies and monosomies involve chromosomes X, Y, 21, 18, and 13 and arise as a result of meiotic nondisjunctions. These aneuploidies are the most common because these four chromosomes have the smallest number of biallelically transcribed genes. The only autosomal trisomies compatible with life are Down syndrome (trisomy 21, 1 in every 670 newborns) (E-Fig. 32-1A),[9,10] Edwards syndrome (trisomy 18, 1 in 7500 newborns), and Patau syndrome (trisomy 13, 1 in every 22,700 newborns). In contrast to trisomies, all monosomies are lethal.

Sex chromosome aneuploidies are found in 1 in 440 newborns. Monosomy X (45,X) in females causes Turner syndrome (Chapter 214), which occurs in 1 in every 4000 female newborns. However, this observed birth rate represents only 1% of all 45,X fetuses because more than 99% of such fetuses result in miscarriage. In most live patients, the 45,X cell line is a mosaic with another cell line that has either a normal karyotype or a structural rearrangement of the X chromosome (e.g., deletion of the short arm, ring chromosome, or isochromosome of the long or short arms). About one in every 1000 males is either 47,XXY Klinefelter syndrome (Chapter 214) or 47,XYY (typically with at most phenotypic manifestations).

STRUCTURAL ABERRATIONS

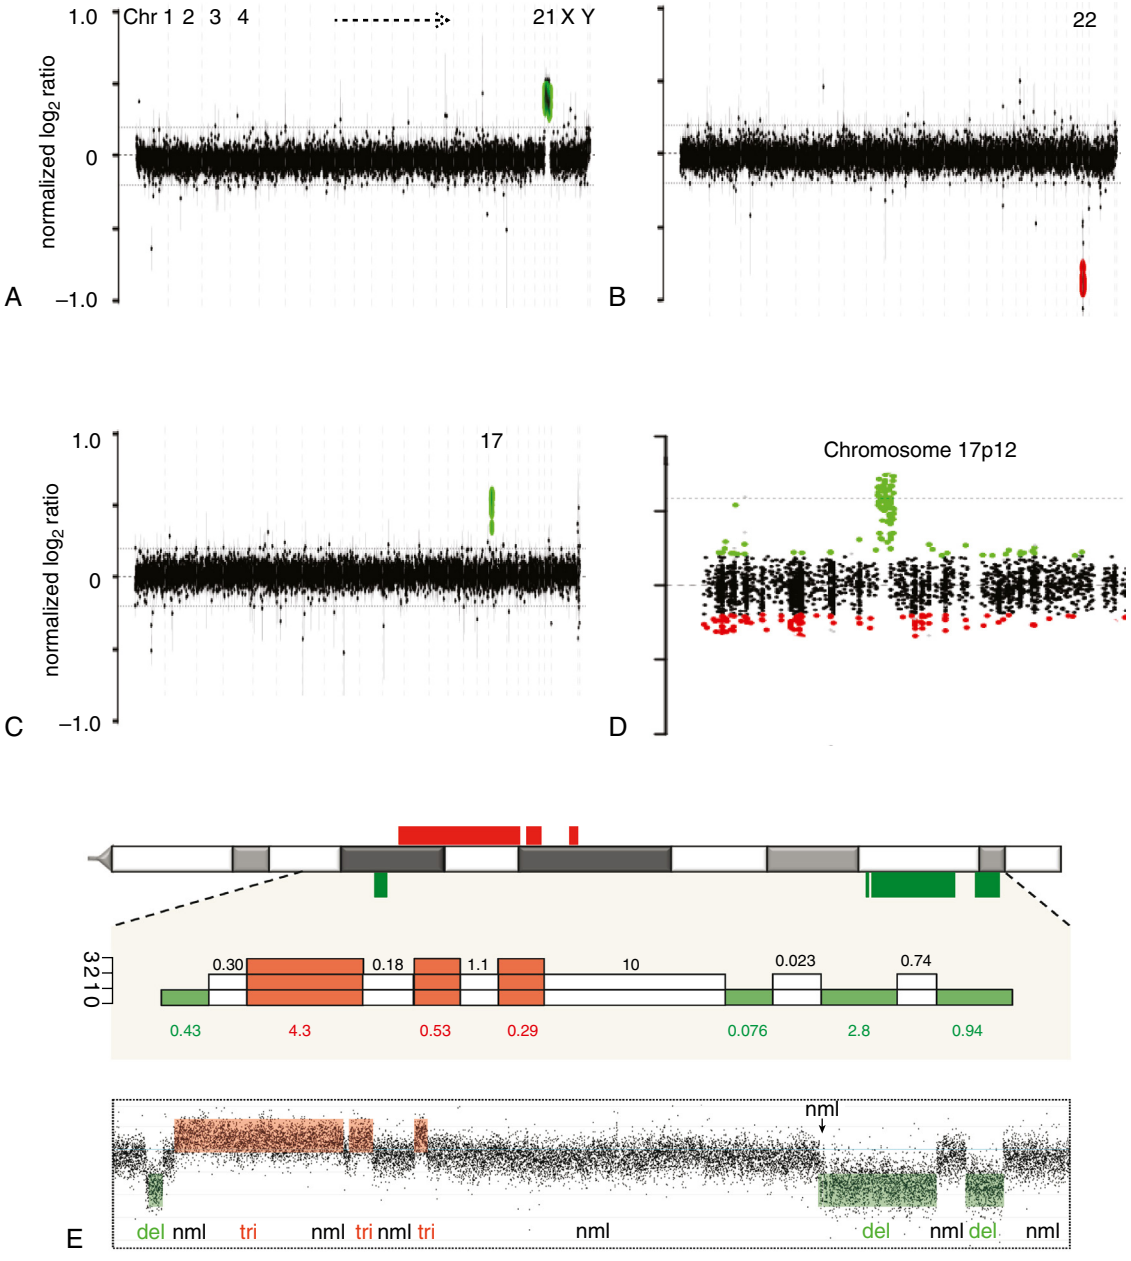
Chromosomal deletions and duplications have been categorized as microscopically visible or submicroscopic, as terminal or interstitial, and as recurrent or nonrecurrent. Balanced reciprocal translocations, which result from an exchange of the DNA material between two chromosomes, are found in about 1 in 600 individuals. During meiosis, the translocation chromosomes segregate and lead to the transmission of either balanced or unbalanced products being transmitted to progeny. The unbalanced products often lead to either spontaneous miscarriage or birth of a child with typically serious clinical consequences. When a fragment of one chromosome is translocated internally into another chromosome's arm, the aberration is termed an insertion or insertional translocation. Insertional translocations occur more than 100 times more frequently than originally recognized. The carrier of a balanced translocation has up to a 50% chance of abnormal progeny. Other less common structural chromosomal abnormalities include inversions, ring chromosomes, isochromosomes, complex chromosome rearrangements, and heterochromatin variants.

ASSAYING GENETIC VARIATION

Genomic assays vary based upon the size of the aberration that is being targeted. Chromosomal aberrations longer than about 5 Mb can be detected by light microscopy (cytogenetics) after specific staining that generates a characteristic banding pattern (e.g., G-banded karyotype analysis). Submicroscopic rearrangements, such as microdeletions or microduplications (30 kb to 5 Mb), can be analyzed using fluorescence in situ hybridization (FISH).[11] Overall, light microscopic techniques are declining in favor of molecular assays but are still necessary to detect balanced rearrangements.

The development of array-based comparative genomic hybridization (array CGH) or single nucleotide polymorphism chip-based testing allows determination of chromosome imbalances and copy number variants, with the level of resolution depending only on the number, size, and distance between the arrayed interrogating probes. Millions of these oligonucleotide probes can be synthesized on one glass slide. Oligonucleotide probes are also used on single nucleotide polymorphism arrays, which, unlike microarray-based CGH, can generate association studies or detect uniparental disomies. The widespread diagnostic use of array CGH and single nucleotide polymorphism chips has not only increased the sensitivity for detecting diseases associated with copy number variants but also has led to the discovery of many additional copy number variant–associated disorders. To detect genomic imbalances, an alternative is a quantitative polymerase chain reaction–based technique called multiplex ligation-dependent probe amplification (MLPA). MLPA provides a simple, rapid, and sensitive method to detect dosage alterations in selected genomic regions.

Most recently, several next-generation sequencing technologies enabled simultaneous and massively parallel DNA sequencing (Chapter 33). These technologies facilitate panel testing (simultaneous assay of multiple genes implicated in a particular phenotype), exome sequencing (the coding regions of the genome), and genome sequencing. Next-generation sequencing methods generate far larger quantities of data at less expense; however, the raw sequence data that are generated from individual amplified DNA template sequences have shorter read lengths, which can be difficult to map uniquely to the genome. Thus, neither exome sequencing nor genome sequencing is truly "whole exome" or "whole genome." Nevertheless, next-generation sequencing of a patient's genome (e.g., 30-fold coverage with respect to the haploid human reference genome sequence) can generate robust and accurate individual genomic evaluation. These next-generation sequencing technologies have led to an explosion in gene discovery and an increasing understanding of the mechanistic bases of



E-FIGURE 32-1. **Assaying copy-number variants (CNVs).** Plots of array-based comparative genomic hybridization from patients with genomic rearrangements. Each "dot" on the plot represents an oligonucleotide that interrogates specific regions of the human genome from chromosome 1 (depicted on *left*) to the sex chromosomes depicted on the *right*). Gain of copy number is depicted in *green,* and loss of copy number is depicted in *red.* **A**, Patient with Down syndrome showing gain (three copies) of chromosome 21. **B**, Patient with congenital heart disease and velocardiofacial syndrome with a 3-Mb deletion of chromosome 22q11.2. **C**, Patient with autosomal dominant sensorimotor neuropathy (CMT1A) with a gain of copy number (duplication) on chromosome 17p12. **D**, Expanded view of the 17p12 duplication shown in **C**. **E**, Complex genomic rearrangement in a pediatric patient with epilepsy and hypotonia showing multiple breakpoints in a single chromosome. The rectangular boxes below the ideogram of the chromosome show copy number of genomic segments, and the numbers depict the size of the copy number variants in Mb. del = deletion; nml = normal; tri = triplication.

genetic disorders. Exome sequencing alone currently has about a 25% yield for clinical diagnosis in patients with phenotypic syndromes of unknown cause—a significant improvement over previously available testing modalities.

Recent advances and the relatively widespread use of array CGH, single nucleotide polymorphism-chips, and next-generation sequencing technologies have transformed the understanding and diagnosis of human disease (Chapter 33). As sequencing becomes less expensive and more available, the understanding of human evolution, disease, and treatment is advancing rapidly.

GENETIC TEST REPORTS

Whereas gene changes formerly were termed "polymorphism" if they are benign and "mutation" if they are disease- or trait-associated, these terms have been replaced. Instead, a gene state different from reference is termed a variant, and the term variant is modified by an adjective such as "benign," "likely benign," of "unknown significance," "likely pathogenic," or "pathogenic."[12] Clinicians will increasingly encounter genetic test reports with descriptors such as "likely pathogenic variant" or "benign variant," or "variant of unknown significance." The involvement of genetic counselors can greatly improve the transmission of genetic information to patients and their families.[13]

As with all forms of medical testing, genetic test results are probabilistic. Some, such as the finding of nonmosaic trisomy 21, confer an extremely high likelihood (for all practical purposes, 100%) of phenotypic abnormality in the patient. Others, such as a novel nonsense variant in a patient with suspected *BRCA1*-related hereditary breast and ovarian cancer susceptibility, may be reported as likely pathogenic.

Distinct variants in a gene can cause the same phenotype (allelic heterogeneity) or distinct phenotypes (phenotypic heterogeneity). By contrast, the same abnormal clinical phenotype can be caused by variants in different genes (genetic or locus heterogeneity). This complexity has led to a proposal to designate human single gene diseases by the dyad of gene and phenotype. For example, *MSH2*-related Lynch syndrome.

Based on the functional consequences, variants are also categorized by their consequences into loss-of-function or gain-of-function variants. The former—also known as hypomorphic (partial loss) or amorphic (null) loss of function (complete loss)—affect the dosage-sensitive or haploinsufficient genes, in which decreased production of a protein is not sufficient for normal function. Gain-of-function variants increase the function or add a new function for the protein (neomorphic), whereas dominant negative variants encode a protein that interacts antagonistically with the normal product from the other allele (antimorphic).

Adult medicine practitioners are increasingly likely to encounter genetic testing results in their practices, whether in a diagnostic setting (e.g., an individual with early onset cancer), a secondary findings setting (e.g., a parent of a child sequenced for autism found to have malignant hyperthermia), or in a direct-to-consumer testing setting (e.g., an unanticipated breast and ovarian cancer susceptibility result from ancestry testing). Familiarity with genetic and genomic test results will allow clinicians to integrate these results seamlessly into their practices and use them to improve the care of their patients.

GENOMICS AND GENETICS AS A NORMAL PART OF MEDICINE

Nongeneticists are sometimes intimidated or concerned about using genetic diagnostics in their practices, and there is some historical basis for this concern. Clinical genetics is associated with a tragic legacy of eugenics, the thoroughly discredited concept that our species should be "improved" by preventing the reproduction of individuals deemed to be genetically undesirable or unfit. The modern clinical practice of genetics seeks to improve the health and lifespan of individuals with genetic disorders, theoretically increasing the frequency of pathogenic variants in the population because successfully treated individuals can live longer and reproduce.[14] The theoretical qualifier is important because, in the larger picture, this effect on the population is much smaller than that of the natural mutation rate. Nevertheless, reproductive genetics can still elicit concerns of eugenic tendencies. Although no overtly eugenic laws or medical practices persist, concerns linger that the very availability of prenatal testing and selective termination, coupled with social and economic pressures against disease and disability, comprise a subtle eugenic bias in reproductive medicine.

The important takeaway from this history and sociology of genetics is that adult medicine clinicians seeking to improve the health of their patients should not hesitate to use genetic and genomic diagnosis and targeted therapeutics because of any lingering fears of the eugenic history of the field. In this respect, genetics is just like any other technologically advanced component of modern medicine. It can have bioethical conundrums (Chapter 2), which may be different from those in other specialties, but these issues are not overall greater or more worrisome than those in other disciplines. Clinicians should ignore protestations that genetics and genomics is somehow exceptional from all other aspects of medicine, or something to be avoided or discouraged. A genetic or genomic test used to diagnose and treat an adult with cardiac disease is no different than a catheter, an ultrasound, or a troponin level—another arrow in the modern biomedical quiver that has great potential to improve health and extend longevity.

APPLICATIONS OF MOLECULAR TECHNOLOGIES TO CLINICAL MEDICINE

GEOFFREY S. GINSBURG

The Human Genome Project, an enabler of the systematic exploration of the molecular underpinnings of disease, has led to the expectation that these insights would lead to a transformation of medical practice. However, most diseases are still defined by their anatomic location and clinical symptoms and are treated with one-size-fits-all therapies that fail to account for the unique biologic background of the individual and of the diseased tissues. Genome-based technologies can probe the molecular architecture of disease and the genetic backgrounds of the individuals who harbor them to improve the potential for more precise diagnostics and therapeutic strategies.[1] The Human Genome Project (https://www.genome.gov/human-genome-project) provided the foundation for precision medicine along with advances in genotyping and sequencing technologies, bioinformatics, systems biology, and computational biology. Today, precision medicine aims to build on this foundation, translating these discoveries into clinical practice, with the ultimate goal of improved health and health care for individuals and for populations.

MOLECULAR TECHNOLOGIES ALONG THE CONTINUUM FROM HEALTH TO DISEASE

In 2015, the United States embarked on a Precision Medicine Initiative to enroll over 1 million people in what is now called the "*All of Us*" research program (https://allofus.nih.gov/). The shared data from sequencing, electronic medical records (EMRs), personal reported information, and digital health technologies provide a platform for assessing the biology of disease as well as a paradigm that will allow for more informed decisions along the continuum from health to disease (Fig. 33-1). Precision health care is now being used in clinical practice across the lifespan (Table 33-1). DNA testing is used for reproductive counseling for couples who are planning a pregnancy and for prenatal testing with sequencing assays of fetal DNA in the maternal circulation to assess for mendelian and developmental disorders. Sequencing in the neonatal intensive care unit (ICU) is becoming more common for diagnoses and determination of treatment options for gravely ill infants. Sequencing is also being used to end the diagnostic odyssey for many children (and some adults) with rare and undiagnosed diseases. For the early assessment of disease risk, family history still may be the most powerful tool. However, genomic risk scores are being defined to complement family history for certain chronic diseases. Although lagging the dramatic decline in cost and increase in throughput of DNA sequencing, technology platforms that measure the "expressed genome" (RNA, proteins, metabolites) are increasingly being used to define physiologic states in response to the environment, to classify disease states, to diagnose current disease, and to predict future clinical outcomes. These approaches, which form the basis for a new molecular classification and taxonomy of disease and diagnosis, can provide more precise ways to screen for

genetic disorders. Exome sequencing alone currently has about a 25% yield for clinical diagnosis in patients with phenotypic syndromes of unknown cause—a significant improvement over previously available testing modalities.

Recent advances and the relatively widespread use of array CGH, single nucleotide polymorphism-chips, and next-generation sequencing technologies have transformed the understanding and diagnosis of human disease (Chapter 33). As sequencing becomes less expensive and more available, the understanding of human evolution, disease, and treatment is advancing rapidly.

GENETIC TEST REPORTS

Whereas gene changes formerly were termed "polymorphism" if they are benign and "mutation" if they are disease- or trait-associated, these terms have been replaced. Instead, a gene state different from reference is termed a variant, and the term variant is modified by an adjective such as "benign," "likely benign," of "unknown significance," "likely pathogenic," or "pathogenic."[12] Clinicians will increasingly encounter genetic test reports with descriptors such as "likely pathogenic variant" or "benign variant," or "variant of unknown significance." The involvement of genetic counselors can greatly improve the transmission of genetic information to patients and their families.[13]

As with all forms of medical testing, genetic test results are probabilistic. Some, such as the finding of nonmosaic trisomy 21, confer an extremely high likelihood (for all practical purposes, 100%) of phenotypic abnormality in the patient. Others, such as a novel nonsense variant in a patient with suspected *BRCA1*-related hereditary breast and ovarian cancer susceptibility, may be reported as likely pathogenic.

Distinct variants in a gene can cause the same phenotype (allelic heterogeneity) or distinct phenotypes (phenotypic heterogeneity). By contrast, the same abnormal clinical phenotype can be caused by variants in different genes (genetic or locus heterogeneity). This complexity has led to a proposal to designate human single gene diseases by the dyad of gene and phenotype. For example, *MSH2*-related Lynch syndrome.

Based on the functional consequences, variants are also categorized by their consequences into loss-of-function or gain-of-function variants. The former—also known as hypomorphic (partial loss) or amorphic (null) loss of function (complete loss)—affect the dosage-sensitive or haploinsufficient genes, in which decreased production of a protein is not sufficient for normal function. Gain-of-function variants increase the function or add a new function for the protein (neomorphic), whereas dominant negative variants encode a protein that interacts antagonistically with the normal product from the other allele (antimorphic).

Adult medicine practitioners are increasingly likely to encounter genetic testing results in their practices, whether in a diagnostic setting (e.g., an individual with early onset cancer), a secondary findings setting (e.g., a parent of a child sequenced for autism found to have malignant hyperthermia), or in a direct-to-consumer testing setting (e.g., an unanticipated breast and ovarian cancer susceptibility result from ancestry testing). Familiarity with genetic and genomic test results will allow clinicians to integrate these results seamlessly into their practices and use them to improve the care of their patients.

GENOMICS AND GENETICS AS A NORMAL PART OF MEDICINE

Nongeneticists are sometimes intimidated or concerned about using genetic diagnostics in their practices, and there is some historical basis for this concern. Clinical genetics is associated with a tragic legacy of eugenics, the thoroughly discredited concept that our species should be "improved" by preventing the reproduction of individuals deemed to be genetically undesirable or unfit. The modern clinical practice of genetics seeks to improve the health and lifespan of individuals with genetic disorders, theoretically increasing the frequency of pathogenic variants in the population because successfully treated individuals can live longer and reproduce.[14] The theoretical qualifier is important because, in the larger picture, this effect on the population is much smaller than that of the natural mutation rate. Nevertheless, reproductive genetics can still elicit concerns of eugenic tendencies. Although no overtly eugenic laws or medical practices persist, concerns linger that the very availability of prenatal testing and selective termination, coupled with social and economic pressures against disease and disability, comprise a subtle eugenic bias in reproductive medicine.

The important takeaway from this history and sociology of genetics is that adult medicine clinicians seeking to improve the health of their patients should not hesitate to use genetic and genomic diagnosis and targeted therapeutics because of any lingering fears of the eugenic history of the field. In this respect, genetics is just like any other technologically advanced component of modern medicine. It can have bioethical conundrums (Chapter 2), which may be different from those in other specialties, but these issues are not overall greater or more worrisome than those in other disciplines. Clinicians should ignore protestations that genetics and genomics is somehow exceptional from all other aspects of medicine, or something to be avoided or discouraged. A genetic or genomic test used to diagnose and treat an adult with cardiac disease is no different than a catheter, an ultrasound, or a troponin level—another arrow in the modern biomedical quiver that has great potential to improve health and extend longevity.

APPLICATIONS OF MOLECULAR TECHNOLOGIES TO CLINICAL MEDICINE

GEOFFREY S. GINSBURG

The Human Genome Project, an enabler of the systematic exploration of the molecular underpinnings of disease, has led to the expectation that these insights would lead to a transformation of medical practice. However, most diseases are still defined by their anatomic location and clinical symptoms and are treated with one-size-fits-all therapies that fail to account for the unique biologic background of the individual and of the diseased tissues. Genome-based technologies can probe the molecular architecture of disease and the genetic backgrounds of the individuals who harbor them to improve the potential for more precise diagnostics and therapeutic strategies.[1] The Human Genome Project (https://www.genome.gov/human-genome-project) provided the foundation for precision medicine along with advances in genotyping and sequencing technologies, bioinformatics, systems biology, and computational biology. Today, precision medicine aims to build on this foundation, translating these discoveries into clinical practice, with the ultimate goal of improved health and health care for individuals and for populations.

MOLECULAR TECHNOLOGIES ALONG THE CONTINUUM FROM HEALTH TO DISEASE

In 2015, the United States embarked on a Precision Medicine Initiative to enroll over 1 million people in what is now called the "*All of Us*" research program (https://allofus.nih.gov/). The shared data from sequencing, electronic medical records (EMRs), personal reported information, and digital health technologies provide a platform for assessing the biology of disease as well as a paradigm that will allow for more informed decisions along the continuum from health to disease (Fig. 33-1). Precision health care is now being used in clinical practice across the lifespan (Table 33-1). DNA testing is used for reproductive counseling for couples who are planning a pregnancy and for prenatal testing with sequencing assays of fetal DNA in the maternal circulation to assess for mendelian and developmental disorders. Sequencing in the neonatal intensive care unit (ICU) is becoming more common for diagnoses and determination of treatment options for gravely ill infants. Sequencing is also being used to end the diagnostic odyssey for many children (and some adults) with rare and undiagnosed diseases. For the early assessment of disease risk, family history still may be the most powerful tool. However, genomic risk scores are being defined to complement family history for certain chronic diseases. Although lagging the dramatic decline in cost and increase in throughput of DNA sequencing, technology platforms that measure the "expressed genome" (RNA, proteins, metabolites) are increasingly being used to define physiologic states in response to the environment, to classify disease states, to diagnose current disease, and to predict future clinical outcomes. These approaches, which form the basis for a new molecular classification and taxonomy of disease and diagnosis, can provide more precise ways to screen for

ABSTRACT

Scientific advances in the genome and data sciences in the past decade have provided an opportunity to deliver health care in a distinctly patient-centered way. Precision medicine uses individual molecular information as well as highly specific clinical information to assess individual risks and develop tailored prevention and treatment strategies. Genome-based technologies (i.e., assays of RNA, proteins, and metabolites) are augmenting diagnosis and treatment as well as changing the taxonomy of disease. Genetic variation associated with drug response, or pharmacogenomics, now provides more precise targeting of therapeutics to an individual's genetic background to optimize the benefit and reduce the risks associated with drug therapies. Despite progress and momentum in the discovery of genomic information with great potential to affect health care, significant challenges and barriers have limited the broad use of genomics in clinical practice. Four of these barriers are: (1) evidence generation; (2) implementation and education; (3) data ownership, sharing, and infrastructure; and (4) participant diversity, engagement, and trust. Until these are challenges are fully addressed, precision medicine may remain a futuristic concept rather than being fully integrated into mainstream medicine.

and to detect disease at its earliest molecular manifestations, often preclinically. In addition, the selection of certain drugs increasingly can be guided by a patient's underlying genetic makeup as well as by the molecular makeup of the disease. Given that a disease's evolution from baseline risk often occurs over many years (see Fig. 33-1), periodic molecular and digital profiling defines a novel form of health care that focuses on health assessments and disease prevention with proactive management rather than the current paradigm of acute intervention and crisis management.

GENOMES, DISEASE, AND TREATMENT

A key question in medicine is to what extent genetic variation influences the likelihood of disease onset, affects the natural history of disease in combination with the environment and social factors, or provides clues relevant to the management of disease. Genome sequencing is providing new approaches for the diagnosis, study, and treatment of disease.

NEWBORN SCREENING, PRENATAL DIAGNOSIS, AND PRE-CONCEPTION CARRIER TESTING

A natural outcome of identifying genes for rare mendelian disorders (Chapter 32) is the application of these findings to earlier detection, at birth (newborn screening), in utero (prenatal diagnosis), or pre-conception (carrier testing).

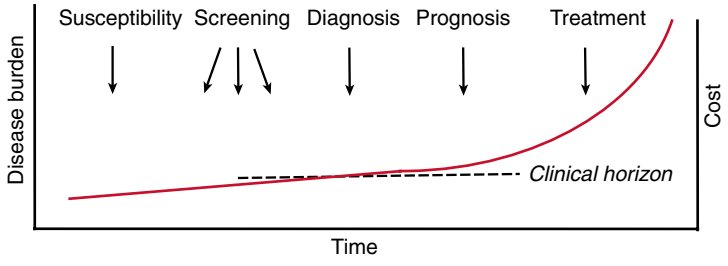

FIGURE 33-1. Use of molecular technologies across the continuum from health to disease. Various molecular technologies may now be used to complement the traditional approach to evaluating health and disease across the lifespan. The *red curve* indicates the course of a chronic disease over time. The *dashed line* indicates when clinical symptoms are manifest. Overall, the goal is to shift the detection and treatment paradigm to the left. (Adapted from Ginsburg GS, Willard H. eds. *Genomic and Personalized Medicine*. 3rd ed. Academic Press; 2016.)

Newborn screening—mandatory, state-supported public health programs meant to protect newborn children by screening them for rare, treatable (and thus preventable) disorders at birth—has been steadily increasing from an average of five conditions in 1995 to a panel of 35 core disorders currently recommended by the U.S. Department of Health and Human Services.[2] Rapid genome sequencing (about 19.5 hours from test to result) has been used to treat patients with undiagnosed and potentially fatal disorders in the neonatal ICU.[3] As the number of conditions considered for newborn screening will undoubtedly grow, rapid sequencing can potentially broaden and foreshorten differential diagnosis, thereby resulting in fewer empirical treatments as well as faster progression to genetic and prognostic counseling.[4,5]

Cell-free fetal DNA circulating in maternal blood can be analyzed by next-generation sequencing technologies to identify fetal aneuploidy from cell-free fetal DNA in maternal plasma. Noninvasive prenatal testing of trisomy 21 eliminates the need for invasive procedures, while also greatly expanding the number of genetic variants that have traditionally been detected in utero.

Before conception, carrier screening enables couples to assess their risk of having a child with a recessive mendelian disorder (Chapter 32) and use this information to guide their reproductive decisions. There are over 1000 rare, *recessive* mendelian disorders for which the underlying genetic mutation is known. Though individually rare, these mutations can have a sizable public health impact considering that each person is estimated to carry on average 2.8 mutations[6] for known severe recessive disorders.

SEQUENCING: A DRIVER OF PRECISION MEDICINE

Genome-wide association studies (GWASs) have identified over 275,000 unique single nucleotide variant trait associations from large cohorts of patients and controls across numerous diseases (https://www.ebi.ac.uk/gwas/). GWAS has been a transformative approach to identifying common genetic variation across the entire human genome in an unbiased fashion, thereby offering an unprecedented opportunity to uncover new biologic pathways of disease. Gene editing technologies using Clustered Regularly Interspaced Short Palindromic Repeats (CRISPR) and Transcription Activator-Like Effector Nucleases (TALEN) are changing the approach to defining the biology of genetic variants discovered by GWAS and sequencing.[7,8]

Since 2001, the cost of sequencing a human genome has dropped from more than $3 billion per genome to $500. Using next-generation sequencing technology, a sequencing laboratory can sequence more than 60 genomes

per day, thereby allowing direct measurement not just of common variants, but also theoretically of all variation in a genome. It is estimated that the population frequency of germline variants is approximately 1 in every 1000 of the 3.2 billion nucleotide positions, thereby giving rise to approximately 3 million variants in a given human genome. The challenge lies in determining the meaning of variants, many of which occur in noncoding regions of the genome whose function is largely unknown, and their potential for causing disease. The significance of the noncoding variants remains poorly understood. As a result, the focus clinically has been on exome sequencing (which examines variation in the coding sequences that constitute 1 to 2% of the genome), in which mutations may have predictable effects on downstream protein structure. Genome interpretation is a key bottleneck in the ubiquitous application of sequencing to clinical medicine.[9] With increasing efforts to encourage data sharing and the creation of interoperable data stores, definitive diagnoses from genomic data should become more common.[10] Of note, the American Colleges of Medical Genetics and Genomics currently defines 73 actionable variants in the human genome (https://www.ncbi.nlm.nih.gov/clinvar/docs/acmg/) that, when found, should be discussed with the patients who harbor them.

RISK PREDICTION FOR COMMON COMPLEX DISEASES

Despite strong statistical associations linking genetic variants with complex diseases in GWAS, the low relative risk of the disease allele (generally <2) limits their use for risk assessment. Notable exceptions include the genetic variations underlying inherited breast cancer syndromes, Lynch syndrome, and familial hypercholesterolemia, for which some variants have enabled preventive treatment or screening of family members as well as their consideration as part of population screening programs.

Despite the advancements in genetic testing, a simple family history continues to be among the best tools to identify risks for common diseases.[11] In fact, for conditions with high heritability, such as cardiovascular disease, family history is a much stronger predictor of disease than any single or combination of genetic/genomic markers. One model suggests that neither family history nor genetic testing should be used as a standalone but that the real power for disease prediction, risk assessment, and differential diagnosis comes from their combined use. Recently, polygenic risk scores have been derived from GWAS and sequencing data to enhance the prediction of genetic susceptibility of individuals to disease. Polygenic risk scores for an individual are calculated as weighted counts of thousands of risk variants that they carry, where the risk variants and their weights have been identified in GWASs. Whether polygenic risk scores are ready for clinical use is a matter of debate because many of them have been derived on data from individuals of European ancestry and may not apply to other ancestral groups. In addition, the utility of polygenic risk scores has not always been compared with more traditional risk calculators or family history, so it is not clear whether polygenic risk scores are superior to other risk assessment tools that are already available clinically.

CLINICAL SEQUENCING FOR RARE DISEASES AND DIAGNOSTIC DILEMMAS

Nearly 7000 mendelian disorders have a known molecular basis (http://omim.org/). However, there are nearly as many suspected mendelian traits for which the molecular basis remains to be identified. The potential for clinical sequencing to find the underlying cause and identify treatment options for these rare, sometimes debilitating diseases has led to the formation of various large national and international rare disease consortia. In some specialized clinical centers and through programs such as the National Human Genome Research Institute's Undiagnosed Diseases Program (http://www.genome.gov/27544402), clinical sequencing is being offered to patients with suspected genetic diseases, the so-called "diagnostic dilemmas." To date, about 30% of the more than 1500 participants have received a diagnosis based on their genome sequencing data.[12,13]

PHARMACOGENOMICS: GERMLINE GENETIC VARIANTS AND DRUG RESPONSE

Over the past decade a plethora of genomic markers of efficacy, adverse events, and dosing of therapeutics have been discovered and recommended for clinical use (see E-Table 33-1), but their uptake into clinical practice has been variable, despite their clear actionability. In some cases, such as with the *HLA-B**5701 genotype for the drug abacavir for the treatment of human immunodeficiency virus (HIV) and *HLA-B**1502 for the antiseizure drug carbamazepine, carriers of these genotypes should avoid the drug entirely to eliminate a specific serious adverse event. In other cases, such as *TPMT* for mercaptopurine or *CYP2C9/VKORC1* for warfarin, adjusting the dose of drug based on genotype can help to avoid toxicity and improve efficacy. *Actionability* is not enough to ensure uptake of pharmacogenomics testing as exemplified with the anti-platelet drug clopidogrel, for which despite having an FDA "black box warning" for efficacy in individuals carrying the *CYP2C19* genetic variant, there is often no clear consensus among physicians on its use. Genetic markers that predict reduced therapeutic efficacy may face a high hurdle for established drugs, unless there is strong evidence of the test's clinical validity and utility.

One barrier to implementation of pharmacogenetic testing in clinical practice is the difficulty in translating genetic laboratory test results into actionable prescribing decisions for affected drugs. The Clinical Pharmacogenomics Implementation Consortium was formed to address this barrier to clinical implementation of pharmacogenetic tests by creating, curating, and posting freely available, peer-reviewed, evidence-based, updatable, and detailed gene/drug clinical practice guidelines (https://cpicpgx.org/). These guidelines follow standardized formats, include systematic grading of evidence and clinical recommendations, use standardized terminology, and are peer-reviewed.

CANCER PHARMACOGENOMICS: SOMATIC SEQUENCING OF TUMOR DNA FOR TARGETING DRUG THERAPIES

Cancer arises as a result of somatic DNA mutations that confer a growth advantage upon the cells in which they have occurred, thereby giving rise to tumors (Chapter 166). Comparison of the genetic profiles of tumors and the surrounding normal tissue can reveal the acquired DNA variations that drive growth and that may reveal targets for treatment. The idea of pairing medicines with specific tumor markers in a targeted fashion was first demonstrated when detailed molecular studies of breast tumors led to the discovery of human epidermal growth factor receptor 2 (HER-2), a biomarker overexpressed in approximately 30% of breast tumors and associated with adverse outcomes. Subsequently, trastuzumab (Herceptin), a humanized monoclonal antibody targeting HER-2, was developed and shown to have increased efficacy in patients whose tumors tested positive. HER-2 testing is now part of the standard evaluation and management of breast cancer (Chapter 183). In the past decade, other examples of cancer therapies with companion diagnostics emerged (https://www.mycancergenome.org/). For example, *EGFR* mutation testing has markedly improved the efficacy of gefitinib and erlotinib, small molecule drugs for the treatment of non–small cell lung cancer (Chapter 177) that target *EGFR*. In metastatic colorectal cancer (Chapter 179), tumors with mutated *KRAS* are usually resistant to treatment with cetuximab and panitumumab, thereby leading the American Society of Clinical Oncologists and the U.S. Food and Drug Administration (FDA) to recommend withholding the drugs in these patients. Next-generation sequencing now allows a comprehensive assessment of actionable tumor markers that indicate the potential for a specific therapeutic to have efficacy in a given tumor (https://www.mycancergenome.org/). In 2011, two cancer drugs received accelerated approval by the FDA for use with a companion diagnostic test: crizotinib for the treatment of patients with locally advanced or metastatic non–small cell lung cancer (Chapter 177) with its companion diagnostic designed to detect the *EML4-ALK* fusion gene, and vemurafenib for the treatment of patients with metastatic or unresectable melanoma positive for *BRAF* V600E mutations (Chapter 188). The International Cancer Genome Consortium (https://www.icgc.org/) and the Cancer Genome Atlas (http://cancergenome.nih.gov/) represent international collaborative efforts to define the spectrum of mutations found in tumors, mapping the genomic landscape of cancer. These efforts provide a foundation from which to develop additional therapeutic strategies against new targets; however, even when successful, the results may be short-lived as therapeutic resistance evolves. Despite the promise of next-generation sequencing, an integrated interdisciplinary approach is needed to select the best therapeutic option for any given patient. Molecular tumor boards have become a powerful platform to foster debate, discussions, and overall communication and decision making for the use of next-generation sequencing data to select therapy.[14]

MICROBIAL SEQUENCING FOR INFECTIOUS DISEASE DIAGNOSIS

In infectious disease, diagnosis of pathogens by next-generation sequencing may supplant the need to first grow microorganisms in culture, previously a major impediment to pathogen identification. For example, in 2003,

sequencing of samples from infected patients with the severe acute respiratory syndrome (SARS) identified the causative agent as a coronavirus. Comparison of sequences of multiple isolates of an organism from a single epidemic gives a picture of the organism's evolution, thereby allowing inference as to where the outbreak began and how the infection spread.[15] Sequencing has been a key for diagnosis, rapid vaccine development, and population health surveillance during the SARS-coronavirus-2 (SARS-CoV-2) pandemic.[16] The clinical application of next-generation sequencing to infectious disease also has been highlighted when the source of a carbapenem-resistant *Klebsiella pneumoniae* outbreak at the National Institutes of Health Clinical Center was identified by sequencing isolates of the bacteria in real time and tracing the source to a single individual who had been discharged 3 weeks earlier.

THE EXPRESSED GENOME

COMPLEX MULTIMARKER GENOMIC TESTS FOR DISEASE DIAGNOSIS AND PROGNOSIS

Beyond DNA sequence, measures of gene expression, proteins, metabolites, and epigenetic changes are being used to generate comprehensive profiles of biologic systems in health and disease. Many of the computational challenges of analyzing these large, complex datasets are being addressed to yield next-generation biomarkers that are multianalyte, diagnostic, prognostic, and predictive. A growing number of marketed tests now typically measure protein or RNA levels, often with complex algorithms, thereby enabling diagnosis and prognosis. One example examines expression of 21 genes in tumor tissue to determine the likelihood of disease recurrence in women with early-stage hormone estrogen receptor–positive breast cancer. The test analyzes expression levels and converts them to a recurrence risk score, which has been shown to help guide treatment in patients, reduce overall health care costs, and improve outcomes and is currently covered by many major insurance companies. Other examples include MammaPrint (Agendia, Inc.), which analyzes the expression of 70 genes to determine whether patients are at high or low risk of breast cancer recurrence; and AlloMap (CareDx, Inc.), an 11 blood gene RNA signature for monitoring rejection following cardiac transplant.

Some, but not all, of the marketed in vitro diagnostic multianalyte index assays have demonstrated analytical and clinical validity, but evidence of clinical utility is usually lagging. Moreover, the very nature of these tests presents challenges to insurers, who grapple not only with limited data on clinical utility, but also how to reimburse such tests that are composed of both a laboratory component and an associated algorithm used to score risk, the latter part being integral to realizing the test's value.

METABOLIC AND PROTEIN PROFILING

Endophenotypes are the various molecular domains that exist at intermediate levels of organization between the genotype and the phenotype, including metabolomics and proteomics.[17] A metabolic profile is very similar to some of the traditional targeted profiles, such as a lipid profile, although it is more comprehensive. Metabolomics measures changes in the metabolic or chemical milieu that are downstream of genomic and proteomic alterations. Humans contain an estimated 5000 or so discrete small molecule metabolites, and the identification of metabolic fingerprints for specific diseases may have particular practical utility for the development of therapies because metabolic changes immediately suggest enzymatic drug targets. Similar to genomics and proteomics, metabolomics may be useful in disease diagnosis, prognosis, and drug development. In particular, metabolomics likely will be a valuable tool in assessing drug toxicity. These tools are being applied to diverse areas such as diabetes, obesity, cardiovascular disease, cancer, and mental disorders.

The large-scale study of proteins, termed proteomics, allows for the identification of proteins and of their differential expression between two physiologic states (e.g., health and a specific disease). Quantitative proteomics, in which global differences in protein abundances are measured, continues to be a priority area for biomarker discovery and molecular medicine. This area has been dominated by stable isotope approaches, but recent label-free quantitative methods rely on the measured intensity of a peptide ion and compare this intensity to intensity in other samples. Label-free methods have the advantage of higher throughput and fewer sample manipulation steps. Multiple- or selected-reaction monitoring of specific peptides within biofluids allows quantitation of absolute abundance of proteins in clinical samples. Although this technology is relatively immature in its applications to human health and disease compared with RNA and metabolic profiling, it is anticipated that these methods, combined with the development of mass spectroscopy technology, will advance proteomics to more routine use in diagnosis, prognosis, and pharmacogenomics within the coming years.[18]

IMPLEMENTING PRECISION MEDICINE IN CLINICAL PRACTICE

Despite progress and momentum in the discovery of genomic information with great potential to affect health care, significant challenges and barriers have limited the broad use of genomics in clinical practice (Table 33-2).[19]

EVIDENCE GENERATION

The adoption of genomic medicine is significantly hampered by gaps in the evidence of its clinical utility or impact on health and economic outcomes. Evidence is needed to demonstrate that genomic approaches deliver improved health outcomes in a cost-effective and affordable manner. As genome-based technologies mature scientifically, mechanisms must be put into place to ensure ongoing assessment and evidence generation of their value to patients, providers, and health systems. The pace of discovery far outweighs the ability to assess the value of each technology using traditional approaches such as randomized controlled clinical trials. Advancing the field likely will be best served by drawing upon a range of evidence sources, including randomized trials, pragmatic clinical trials, observational studies, and mining of data from EMRs.[20]

One strategy for developing the evidence base is to use continuous data collection among diverse populations after a drug or diagnostic test has entered the marketplace. A framework that guides implementation and ensures ongoing evidence generation, either after these products have been approved by regulators and entered the market or across a dedicated genomic medicine implementation network, could ultimately enhance the pace of adoption. Ongoing post-market data capture and evidence development is a paradigm that has been broadly underutilized but could be used to assess the economic impact of genomic medicine approaches.

IMPLEMENTATION OF PRECISION MEDICINE IN HEALTH CARE SYSTEMS

Generating the evidence base for precision medicine requires overcoming many practical and logistic challenges such as the absence of supporting information

TABLE 33-2 CHALLENGES AND SOLUTIONS TO ENABLE PRECISION MEDICINE IN PRACTICE

CHALLENGE	POTENTIAL SOLUTIONS
Evidence generation	• Balance the use of evidence generated from randomized controlled trials, the analysis from large datasets, and observational studies • A framework that ensures ongoing evidence generation once products have been approved by regulators and entered the market • Final regulatory and payer approval contingent on the inclusion of a health economic analysis
Implementation and education	• Standardized structured data and common data elements in EMRs • A centralized global genomic medicine toolbox to include optimized decision support tools • Increased investment in implementation science and diffusion research, as well as the outcomes and public health impact • Incentives to encourage adoption of precision medicine best practices by clinicians and health care delivery systems • Modular genomic medicine education programs for clinicians • Integration of genomics into core curricula in professional training • Educational programs, beginning at early educational stages, to emphasize precision and related concepts
Data ownership, privacy, and sharing	• Incentives among the public, private industry, academics, and government • Data governance and ownership frameworks • Privacy measures and risks associated with data breaches
Participant diversity, engagement, and trust	• A research agenda to understand participant preferences, beliefs, literacy, and values in precision medicine research and clinical care • Programs should reach out and engage underserved populations • Community advisors and ambassadors

Adapted from Ginsburg GS, Finkelman E, Balatbat C, et al. *Precision Medicine: A Global Action Plan for Impact*. Doha, Qatar: World Innovation Summit for Health; 2016.

technology (IT) infrastructure, data standards and interoperability, decision support technology, and funding for implementation and translational research. EMRs can enable linkage between genetic information and other health information to produce new understandings of health and disease. EMRs have been suggested as a possible solution for delivering actionable genomic information to providers. However, even where EMRs are available, they are largely unprepared to handle genomic information. Compounding this problem is a lack of standards for how such data should be stored. This challenge is referred to as interoperability, or the ability of IT programs to communicate with other systems both in terms of the data and codes they contain and the operating systems they use. In addition, standards for structured data, or common data elements, to be captured in EMRs must be developed. Having these structured data will allow datasets to be aggregated across health systems and research cohorts to be created across institutions. An example of work being done to enable the integration of genomic information is the DIGITizE Action Collaborative of the National Academies of Science, Medicine and Engineering (http://www.nationalacademies.org/hmd/Activities/Research/GenomicBasedResearch/Innovation-Collaboratives/EHR.aspx).

Clinical decision support is becoming more relevant as the sheer volume of information providers need to have "just in time" increases and also as clinical conditions continue to be subdivided and treated differently. Clinical decision support has the power to use genetic information to guide decision making, reduce cognitive load, and potentially limit medication errors. Clinical decision support, empowered by a robust IT infrastructure, represents an important approach for ensuring adherence to evidence-based precision medicine in clinical practice as well as a platform from which to share clinical success and cost-savings information.

Education of key stakeholder groups is a critical need for implementation and adoption of genomic medicine technologies. Most health professional educational programs are devoid of the practical information for understanding the use of genomic medicine testing, interpretation of the results, and how to counsel patients. These gaps must be filled for both the workforce currently in practice and for the workforce of the future.

DATA OWNERSHIP, PRIVACY, AND SHARING

Data sharing among health care systems, industry, researchers, clinicians, and patients is integral to evidence generation and to advancing the understanding of health and disease. Prototypes for sharing genomic and clinical data on a centralized platform are being developed (E-Table 33-2), but the IT costs prohibit some health care systems from participating in data sharing. As a result, underserved populations may be underrepresented in or completely absent from the shared datasets. Amassing larger and more diverse datasets and sharing these data with smaller or resource-limited health settings will be critical for their inclusion in precision medicine strategies in the future.

Policy and regulatory frameworks must address participants' concerns related to data ownership and privacy. Given the intrinsic identifiable nature of genomic
21 data, patients have concerns about their privacy and rights.[21] Because obtaining participant consent is a necessary first step to gathering research data, the informed consent process could be made more standardized and streamlined globally, including implementing and standardizing nontraditional electronic consent tools to make it easier on patients and researchers.

Legislation prohibiting discrimination based on genetic information, such as
22 the Genetic Information Nondiscrimination Act of 2008[22] in the United States, is an important step toward allaying the public's fears of how their (genomic) data might be used. The informed consent process might be further enabled by a framework that (1) addresses the risks to and concerns of patients and the general public, (2) provides information on what privacy protections are currently in place, and (3) provides information on how data sharing promotes the public good.

PARTICIPANT ENGAGEMENT AND TRUST

Participants are truly the key enablers of precision medicine. Their genomic and personal information contributes to research and eventually to evidence generation. Their appetite for data sharing will encourage implementation of genomics into health care. Their trust that personal data will be used effectively and ethically will enable data sharing. Initiatives that pursue deeper engagement between participants and the clinical care and research components of their various health care systems will enable the field to progress. Engagement is being enhanced through several channels, including traditional education approaches (for providers, patients, and the general public) and with patient and health advocacy organizations.

Due to the longitudinal nature of evidence generation in precision medicine, continuous efforts should be made to engage and update participants on the existing and/or potential risks and benefits of participating in precision medicine research to help secure an ongoing research partnership with participants and their families. Engagement strategies with the participant should pay attention to the diversity of health literacy and numeracy (such that risk information, for example, can be understood) of the population. The degree to which individuals engage with research and clinical care depends on their ability to access and understand their health care information, relevant consent documents, and the potential impact of testing and treatment on their clinical outcomes. Efforts could be made to not only ensure that information is provided to participants (perhaps through patient portals connected to precision medicine–enabled EMRs), but also to ensure that such materials are context sensitive and culturally appropriate. Genomic and precision medicine may exacerbate existing health disparities; therefore, additional efforts will be required to ensure that diverse ethnic and cultural groups are informed, engaged, and represented to ensure maximum impact of precision medicine to improve health outcomes.[23] A recent framework for a social contract between 23
genomic medicine researchers and participants in the United Kingdom may be a useful model for both researchers and clinicians.[24] 24

REGENERATIVE MEDICINE, CELL THERAPY, AND GENE THERAPY

LIOR GEPSTEIN AND KARL SKORECKI

CELL THERAPY

DEFINITION

A remarkable clinical need exists for the development of methods to facilitate the regeneration of injured or diseased tissues and organs. This need stems from the unrelenting prevalence of trauma, congenital disorders, ischemia, and degenerative processes, which becomes increasingly urgent as the global population expands and ages. Cancer also is tied to this field, both directly (replacement of lost vital organ function as a result of cancer invasion or treatment modalities, cell-based delivery of cancer immune and gene therapies) and indirectly (e.g., role of stem cells in cancer pathogenesis and risk of tumorigenesis in stem cell–based therapies). Recent developments in stem cell biology, molecular interventions, biopolymers, and other related biological and engineering disciplines have paved the way to the emerging research and clinical discipline of regenerative medicine.

REGENERATIVE MEDICINE

Regenerative medicine seeks to harness methods for the replacement or repair of dysfunctional cells, tissue, or organs in an attempt to restore normal function. It therefore draws upon therapies from the three conventional pillars of medical therapeutics (pharmaceuticals, biologics, and medical devices) as well as from the newest technology platforms, namely, cell therapy, tissue engineering, and molecular therapies. The long-term goal of regenerative medicine is to replace the lost functions of tissues and organs, and, consequently, to develop curative strategies for unmet clinical needs such as diabetes, heart failure, chronic kidney disease, traumatic and ischemic tissue loss, and neurodegenerative disorders, among others.

Cell Therapies

Cell therapies involve the application of cells to achieve a therapeutic benefit. Although achieving tissue and organ regeneration through cell replacement represents an important goal of cell therapy, additional therapeutic benefits could be obtained by immunomodulatory effects (e.g., for prevention of graft-versus-host disease), by acting as a vehicle for the delivery of genes or gene

REGENERATIVE MEDICINE, CELL THERAPY, AND GENE THERAPY

LIOR GEPSTEIN AND KARL SKORECKI

CELL THERAPY

DEFINITION

A remarkable clinical need exists for the development of methods to facilitate the regeneration of injured or diseased tissues and organs. This need stems from the unrelenting prevalence of trauma, congenital disorders, ischemia, and degenerative processes, which becomes increasingly urgent as the global population expands and ages. Cancer also is tied to this field, both directly (replacement of lost vital organ function as a result of cancer invasion or treatment modalities, cell-based delivery of cancer immune and gene therapies) and indirectly (e.g., role of stem cells in cancer pathogenesis and risk of tumorigenesis in stem cell–based therapies). Recent developments in stem cell biology, molecular interventions, biopolymers, and other related biological and engineering disciplines have paved the way to the emerging research and clinical discipline of regenerative medicine.

REGENERATIVE MEDICINE

Regenerative medicine seeks to harness methods for the replacement or repair of dysfunctional cells, tissue, or organs in an attempt to restore normal function. It therefore draws upon therapies from the three conventional pillars of medical therapeutics (pharmaceuticals, biologics, and medical devices) as well as from the newest technology platforms, namely, cell therapy, tissue engineering, and molecular therapies. The long-term goal of regenerative medicine is to replace the lost functions of tissues and organs, and, consequently, to develop curative strategies for unmet clinical needs such as diabetes, heart failure, chronic kidney disease, traumatic and ischemic tissue loss, and neurodegenerative disorders, among others.

Cell Therapies

Cell therapies involve the application of cells to achieve a therapeutic benefit. Although achieving tissue and organ regeneration through cell replacement represents an important goal of cell therapy, additional therapeutic benefits could be obtained by immunomodulatory effects (e.g., for prevention of graft-versus-host disease), by acting as a vehicle for the delivery of genes or gene

ABSTRACT

The significant developments in the areas of stem cell biology, molecular interventions, and tissue engineering have opened a new medical discipline, regenerative medicine. This therapeutic approach seeks to replace or repair lost or dysfunctional cells, tissue, or organs using adult-origin or pluripotent stem cells. Proven or still experimental procedures include the use of bone marrow- and blood-derived stem/progenitor cells; delivery of extracellular vesicles, the activation of tissue-specific resident stem/progenitor cells or induction of cell proliferation to induce endogenous regeneration; the use of transcription-factor reprogramming to convert one cell type into another; and the engraftment of fetal tissue or ex vivo predifferentiated cell derivatives from pluripotent stem cells. An alternative therapeutic approach is gene therapy, which involves the transfer of genetic material (DNA, siRNA, or modified RNA) into cells in order to correct inherited disorders through the expression of the missing proteins, or to alter cellular function for treatment of nongenetic diseases through overexpression or inactivation of a specific protein. Recent clinical trials of gene therapy have shown encouraging benefits and an excellent safety record. Ongoing studies aim to move from uncontrolled overexpression of the missing protein to directly correcting the mutation at the DNA level through the use of gene-editing strategies such as the CRISPR-Cas9 system.

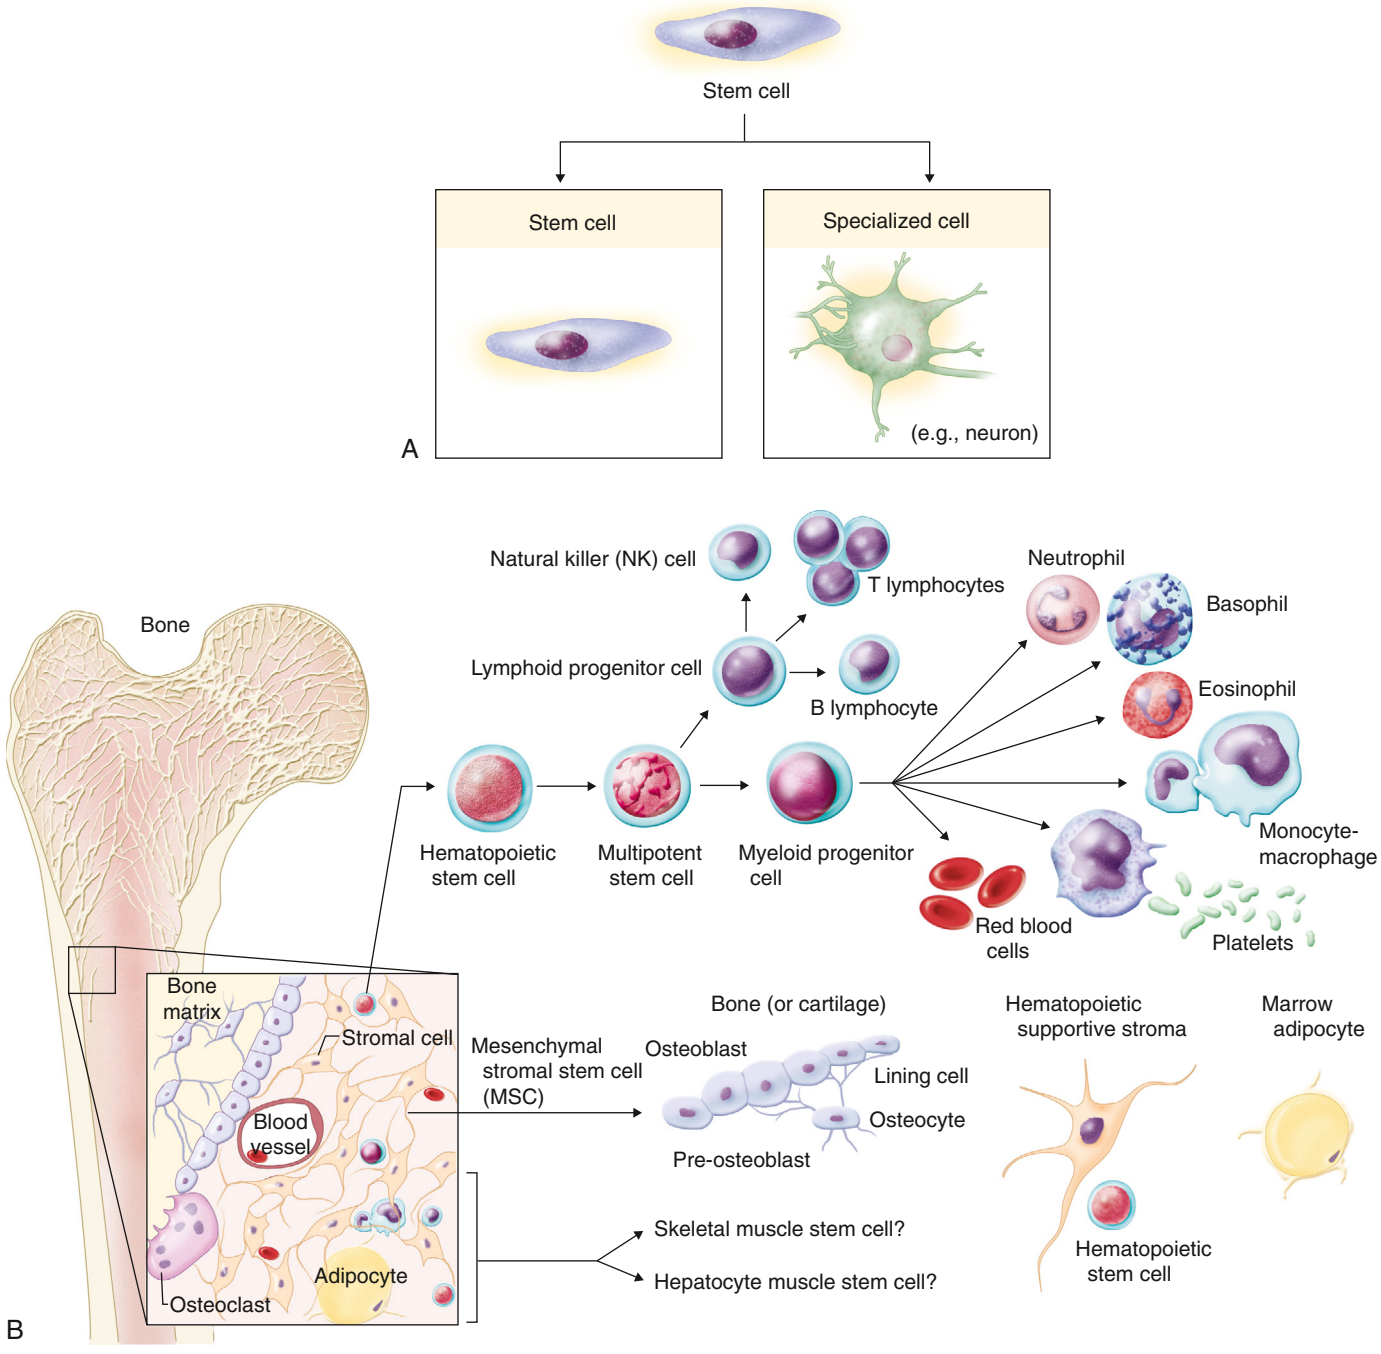

FIGURE 34-1. **A, Asymmetrical cell division. Although this property was considered a required characteristic for stem cells based on their original description in the adult hematopoietic system, not all cell types currently named as stem cells necessarily display this property. For instance, human embryonic stem cells divide by symmetrical cell division. B, Adult stem cells. Adult stem cells can be multipotent and have the capacity to differentiate into a limited number of different cell types, often restricted to a given tissue or organ system, as in the case of adult hematopoietic or epidermal stem cells. Two stem cell types have been isolated from adult bone marrow: the hematopoietic stem cell (HSC) that can give rise to all blood cell types and the supporting mesenchymal stromal cell (MSC). MSCs have immunomodulatory effects and can give rise to some differentiated cell types.**

products, and by the genetic engineering of immune cells (e.g., in chimeric antigen receptor [CAR] T-cell–based therapies).

Stem Cells

Stem cells possess two defining properties: (1) the capacity for self-renewal and (2) the ability to differentiate into cell types with specialized cellular functions (Fig. 34-1A). Their effects may occur through the process of asymmetrical cell division at the individual stem cell level or at the cell population level wherein a subset of cells differentiates and the remaining stem cells remain dormant or replicate themselves as stem cells. After asymmetrical cell division, non–stem cell derivatives may either generate a pool of organ system–restricted, transit-amplifying cells with enhanced proliferative capacity or continue to differentiate by epigenetic and gene expression profile changes until reaching the terminally differentiated state. For example, bone marrow cells are capable of reconstituting the adult hematopoietic system (Fig. 34-1B). These hematopoietic stem cells constitute the basis for hematopoietic stem cell transplantation, the only form of stem cell therapy performed routinely in clinical practice (Chapter 163).

The different stem cell types can be classified based on the protein or transcription factors they express, but also according to their replicative capacity (limited versus unlimited), the scope or potency of differentiation (e.g., pluripotent, multipotent, oligopotent, unipotent), and their place in the life history of the organism (developmental or post-developmental).

ADULT (POSTNATAL) STEM CELLS. After birth, many tissues are thought to contain a subpopulation of cells with the capacity for extended self-renewal, combined with the ability to differentiate into more mature cell types with specialized functions (Fig. 34-1). Adult stem cells, thought to represent less than 0.01% of the total number of cells, are located in specialized supportive

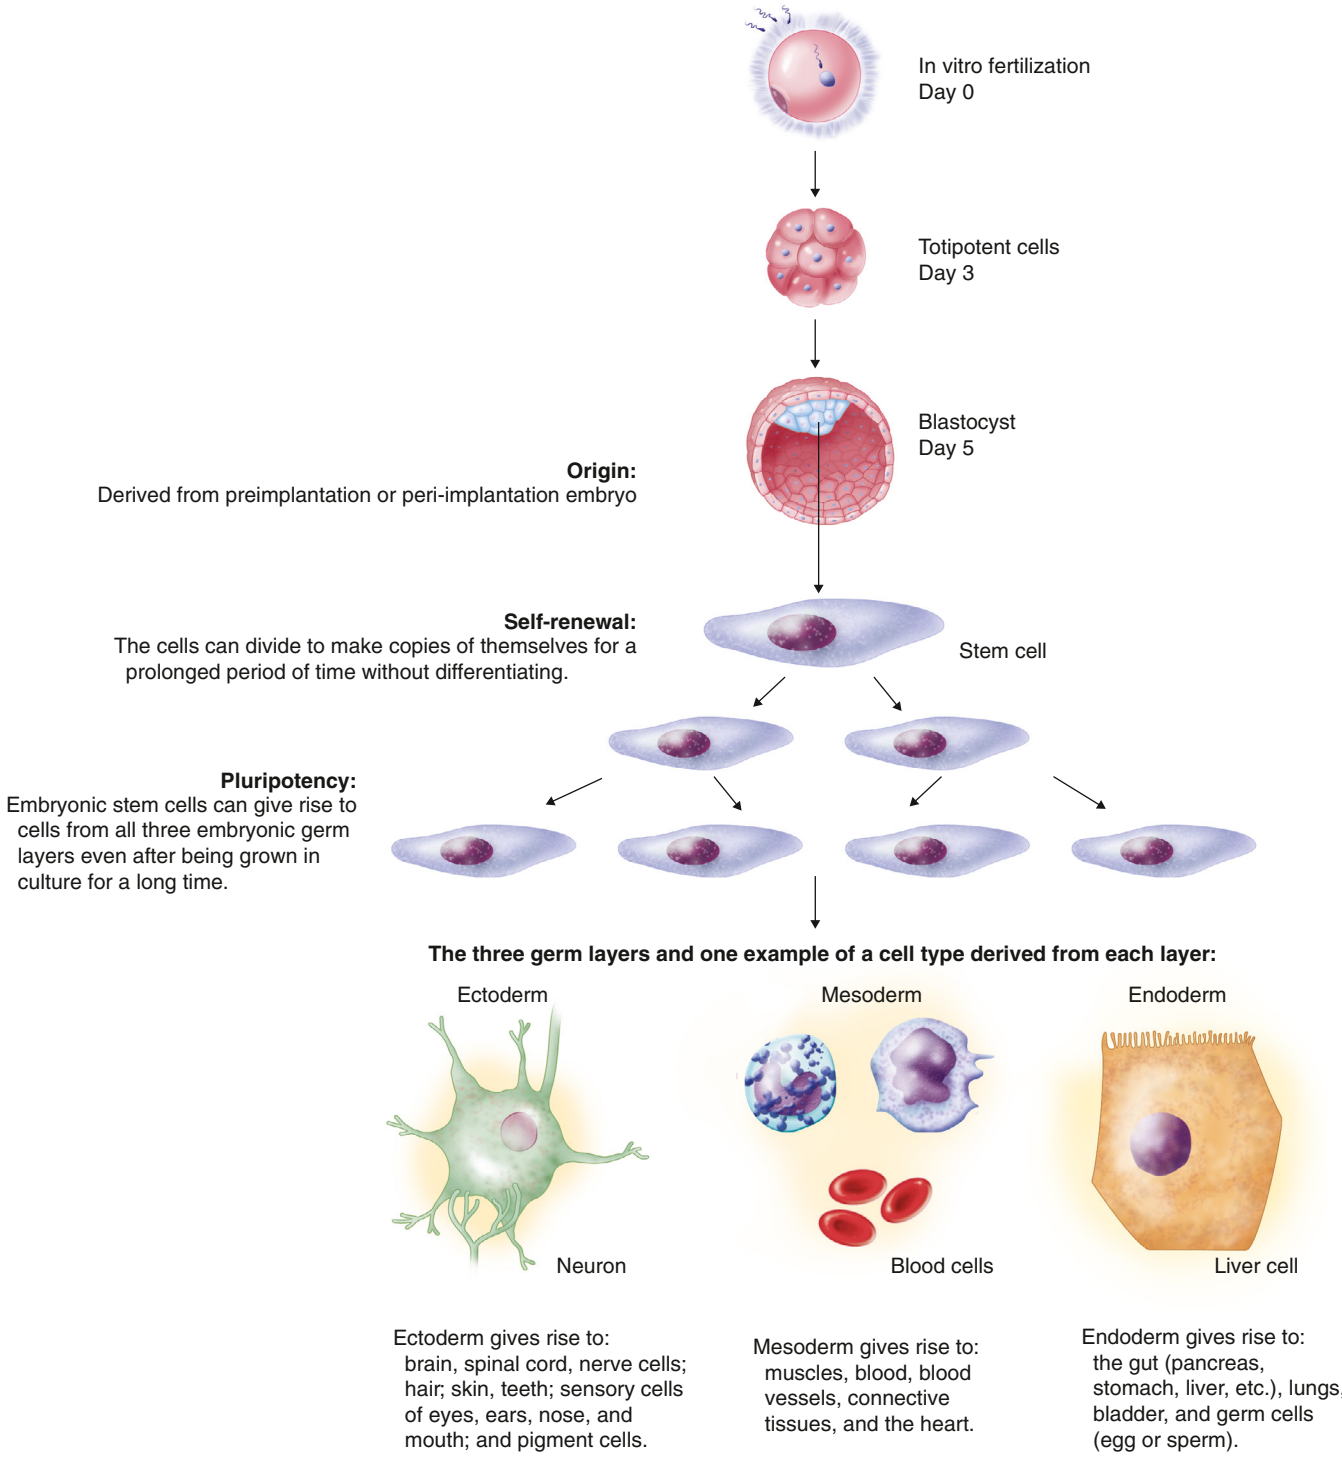

FIGURE 34-2. Embryonic stem cells. Totipotency refers to the capacity to differentiate into all cell types in an organism, including extraembryonic tissues, placenta, and umbilical cord, a property confined to the fertilized egg itself, including the cells derived from the first few cell divisions after fertilization. Pluripotency refers to the capacity to differentiate into all the specialized cell types derived from the three germ layers (ectoderm, mesoderm, endoderm) of the developing embryo and is a hallmark feature of embryonic stem cells, derived from the inner cell mass of the preimplantation blastocyst.

niche compartments and respond to cues in their local microenvironment. Adult tissues reported to contain putative stem cells include bone marrow (hematopoietic and mesenchymal compartments), blood vessel endothelium, dental pulp, epithelia of the skin, adipose tissue, digestive system, cornea, retina, testis, and liver. Similar stem/progenitor cells were also reported in organs historically not thought to contain such cells, such as the central nervous system. Whether adult stem cells represent remnants of developmental stem cells that persist into adulthood for the purposes of organ maintenance and repair or represent a distinct cell type dedicated for this latter purpose is not clear. Importantly, in many organs, despite the presence of such tissue-specific stem cells, their regenerative capacity is still inadequate to deal with massive cell loss, such as occurs following ischemic brain injury.

EMBRYONIC AND INDUCED PLURIPOTENT STEM CELLS. In contrast to adult stem cells that have relatively limited differentiation potency, cells in the developing preimplantation embryo retain the capacity to differentiate into all tissues in the body. Consequently, human embryonic stem cells, which can be isolated from the inner cell mass of human blastocysts generated for in vitro fertilization, can be propagated indefinitely in the undifferentiated state using special culture conditions, while retaining the capacity to differentiate into cell derivatives of all three germ layers (ectoderm, mesoderm, and endoderm) (Fig. 34-2). Using combinations of different growth factors, human embryonic stem cells can be induced to differentiate into several cell types, including neurons and glia, cardiomyocytes, vascular endothelial and smooth muscle cells, pancreatic β-cells, hepatocytes, and blood cells (e.g., platelets, red blood cells).

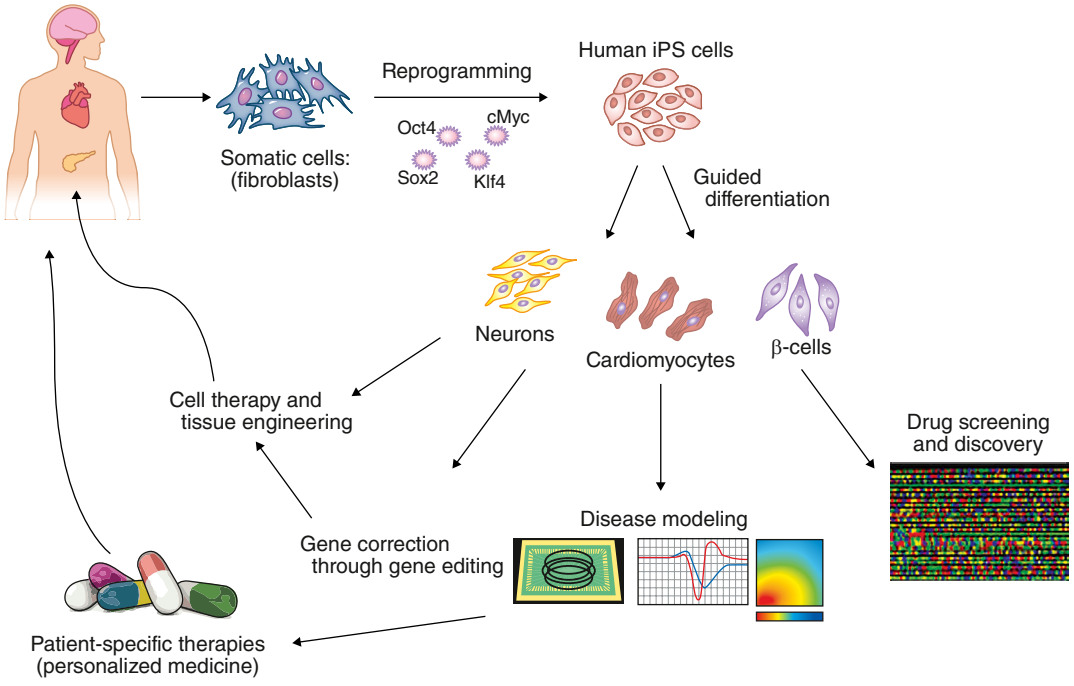

FIGURE 34-3. Potential applications of human induced pluripotent stem cells (hiPSCs). Patient-specific hiPSCs can be generated by reprogramming adult-somatic cells (e.g., fibroblasts) with a set of transcription factors and then coaxing them to differentiate into a variety of cell lineages. The patient-specific hiPSC cell derivatives can then be transplanted back into the patient in an autologous manner for regenerative medicine applications. In a similar manner, disease/patient-specific hiPSC-based models of inherited disorders can be generated ("disease-in-a-dish models") and used to improve the understanding of genetic disorders, to develop drugs, and to optimize patient-specific therapies. Gene editing techniques can be used to correct mutations and for transplantation of healthy cells.

One of the limitations in using human embryonic stem cells is the inability to derive such cells from adult individuals, thereby preventing their utilization in a patient-specific manner. This limitation was overcome with the introduction of the human induced pluripotent stem cell technology. This approach allows adult somatic cells (such as fibroblasts or blood cells) to be reprogrammed into pluripotent stem cells through the transient expression of a set of transcription factors linked to pluripotency. The human induced pluripotent stem cells generated can then be coaxed to differentiate into a wide variety of cell types. Importantly, since hiPSCs can be generated in a patient-specific manner, the technology can be used to develop autologous cell-replacement strategies that can preempt immunologic rejection, to generate patient/disease-specific models of genetic disorders, and to establish screens for drug testing and drug discovery (Fig. 34-3).

Conceptual Cell Therapy Approaches for Regenerative Medicine

Historically, the field of cell therapy can be traced to the transfusion of blood and blood products, solid organ transplantation, in vitro fertilization, and bone marrow transplantation. Nevertheless, beyond the aforementioned therapies and the recent emergence of CAR T-cell therapy for hematologic malignancies, additional cell therapy approaches are considered experimental and are still at different stages of preclinical and clinical development (Fig. 34-4).[1]

BONE MARROW–DERIVED STEM/PROGENITOR CELLS AND MESENCHYMAL STROMAL CELLS. Studies of bone marrow–derived hematopoietic or mesenchymal stem cells were based initially on the assumption that these adult stem cells may display some degree of plasticity, thereby allowing them to transdifferentiate into the relevant cell types (such as heart cells, nerve cells, and liver cells) following engraftment into the appropriate tissue environment. Although mounting evidence suggests that such transdifferentiation probably does not occur to a significant extent, many of these studies reported varying degrees of functional improvement in different organs. It now seems that the clinical benefit relates to growth factors that are secreted by the engrafted cells ("paracrine hypothesis") and augment endogenous tissue repair, improve tissue vascularization, modulate inflammation, and protect tissues at risk. Nevertheless, despite numerous trials for several indications, no mesenchymal stromal cell therapies are currently FDA approved in the United States.

DELIVERY OF EXTRACELLULAR VESICLES. Extracellular vesicles are intrinsic mediators of intercellular communication and allow functional transfer of biomolecules (lipids, proteins, DNA, mRNA, and microRNAs) between diverse locations.[2] Extracellular vesicles represent a collective term for vesicles that are secreted or shed by cells and can be categorized into groups, either by their size or mechanisms of formation and release. Examples include apoptotic bodies (1 to 5 μm), microparticles (100 to 1000 nm), and exosomes (<100 nm). Extracellular vesicles have attracted considerable interest both as potential biomarkers for disease and as therapeutic agents.

Many stem cells may exert their beneficial effect in tissue repair/regeneration by a paracrine effect, potentially acting by transferring biologically active molecules via extracellular vesicles. Delivery of extracellular vesicles may possess several advantages over stem cell therapy, such as reduced cost, easier manufacturing and delivery, and limited immunogenicity. Extracellular vesicles can also be used as a novel drug delivery approach by engineering the cells from which they are created to confer unique properties tailored for specific applications.

DELIVERY OR ACTIVATION OF TISSUE-SPECIFIC STEM CELLS OR INDUCTION OF CELL PROLIFERATION. In contrast to the conventional dogma, recent evidence suggests that several organs believed to lack regenerative capacity (such as the brain, pancreas, and kidney) do possess such ability, albeit at a limited capacity. Whether this capability is due to the presence of tissue-specific stem/progenitor cells or due to the replication capability of terminally differentiated cells is still a matter of debate.

Significant efforts have been made in recent years to isolate such putative tissue-specific stem/progenitor cells based on the expression of general or specific stem cell markers or unique culturing properties. Current efforts to utilize these findings for regenerative medicine are focused either on the isolation, ex vivo expansion, and transplantation of such putative stem/progenitor cells back to their respective native organs or on the augmentation of their endogenous reparative potential in vivo.

The final strategy aims to boost endogenous organ repair through the replication of terminally differentiated tissue-specific cells. Such strategies can either augment the inherent physiologic capability of a given organ (for example, insulin secretagogues for pancreatic β-cells) or attempt to induce replication in cells that have already withdrawn from the cell cycle, such as in the case of cardiomyocytes. Such regeneration strategies in the heart, for example, focus on attempting to replicate molecular and cellular pathways involved in the transient regeneration capacity reported in the neonatal mammalian heart[3] or by genetic approaches promoting adult cardiomyocytes to reenter the cell cycle.

ENGRAFTMENT OF HUMAN FETAL TISSUES OR XENOTRANSPLANTATION USING GENETICALLY MODIFIED ANIMALS. The most straightforward

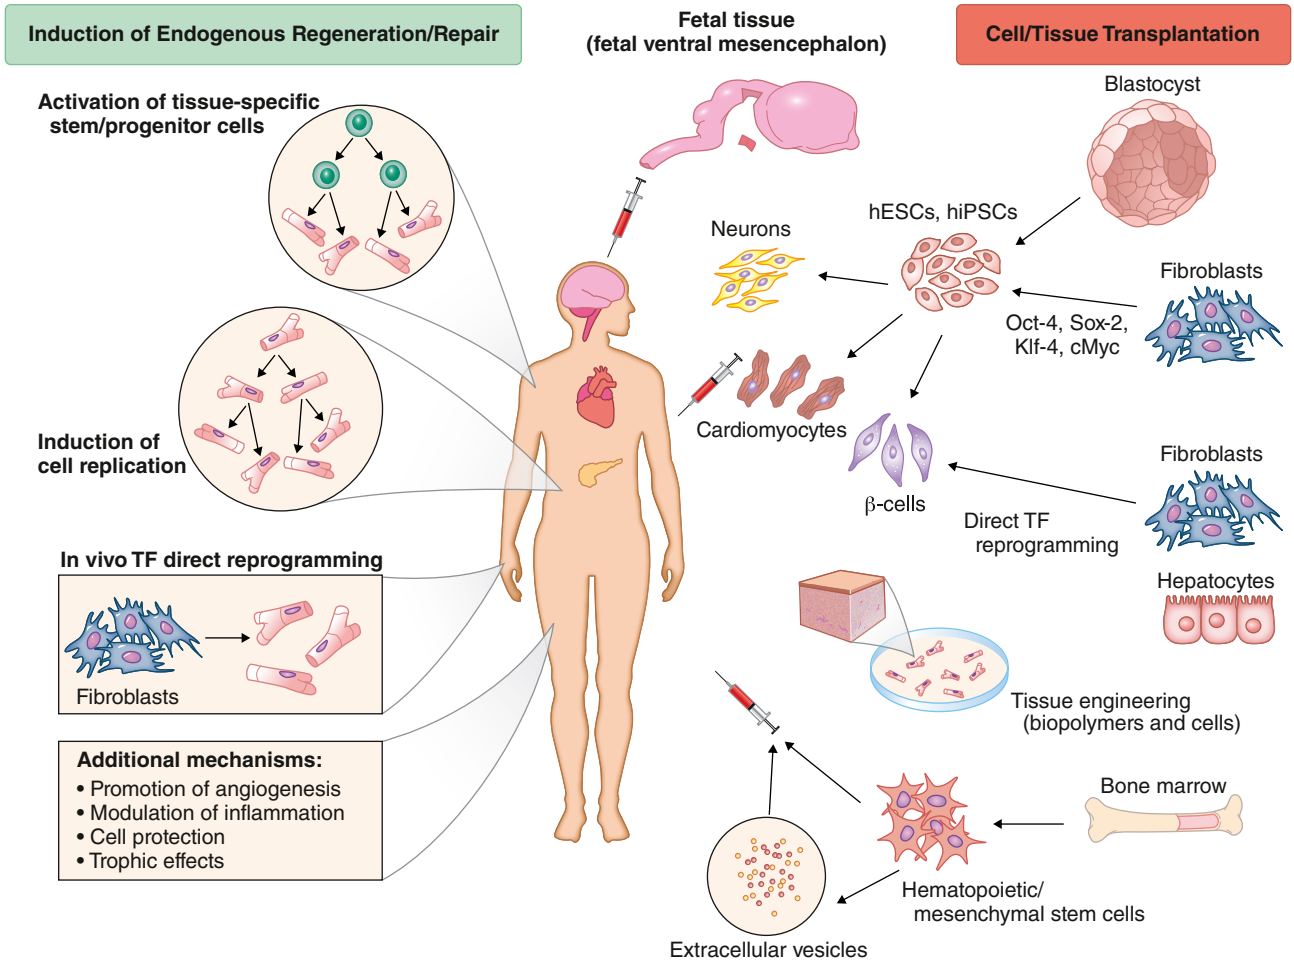

FIGURE 34-4. Conceptual framework for regenerative medicine approaches. These strategies can be divided into those attempting to augment endogenous regeneration or those focusing on transplantation of cells. The former could be achieved through the activation of putative tissue-specific stem/progenitor cells, through induction of cell replication, by in vivo transcription factor (TF)–based direct reprogramming (directly converting one somatic cell type such as fibroblasts into another), and by several other indirect means (e.g., modulation of inflammation, induction of angiogenesis, trophic effect, protection of tissue at risk). Cell sources that can be used for cell transplantation include fetal tissues (e.g., dopaminergic-rich fetal ventral mesencephalon for Parkinson disease), pluripotent stem cell (hESCs and hiPSCs)–derived cell lineages, and somatic cells that can be generated ex vivo by direct transcription factor–based reprogramming of fibroblasts. More recently, delivery of extracellular vesicles (EVs) derived from such cell sources were suggested as a potential alternative to cell therapy. Finally, the aforementioned cell sources can be combined with biopolymers as a tissue-engineering strategy. hESC = human embryonic stem cell; hiPSC = human induced pluripotent stem cell.

approach for organ repair would be to replace the missing cells/tissues/organs with identical counterparts. During prenatal human development, cells of fetal origin often show enhanced proliferative capacity as well as the ability to differentiate into more than one type of mature or specialized cell. Moreover, animal studies have demonstrated that transplantation of tissues harvested from developing organs may give rise to entire functioning organs such as kidneys, lungs, and pancreas. Nevertheless, to date, the only fetal-derived cells that have been used in human clinical applications are the dopaminergic cells derived from the developing fetal nervous system for the treatment of Parkinson disease, with conflicting evidence for success (Chapter 378).

An alternative to the use of human tissue/organ donors may be xenotransplantation, focusing on the use of transgenic pigs as sources for organ transplantation. Several genetically modified pig lines have been generated (most recently using the CRISPR/Cas9 genome editing system), aiming to overcome the main obstacles of immune rejection of the xenografts, physiologic incompatibilities, and transmission of zoonotic pathogens. These advancements have allowed proof-of-concept implantation of kidneys derived from such genetically modified pigs into two legally dead people with no discernible brain function.[4] More recently, a heart from a genetically modified pig was implanted in a patient who had terminal heart failure and was not a candidate for conventional heart transplantation.[5] The pigs were genetically modified to knock out three endogenous swine genes and to knock in six human genes, thereby reducing the immune rejection of the xenografts and particularly the hyperacute rejection associated with the presence of highly immunogenic glycoprotein derivatives in the vasculature of the pig's organs.

TRANSPLANTATION OF EX VIVO DIFFERENTIATED HUMAN PLURIPOTENT STEM CELLS. Numerous preclinical studies have demonstrated the ability of human embryonic stem cell derivatives to engraft, survive, and improve organ performance in a wide spectrum of relevant animal disease models (including, for example, heart failure, Parkinson disease, and diabetes). Nevertheless, the inability to create patient-specific human embryonic stem cells from adult individuals, the ethical issues arising from destructive use of human embryos, and the anticipated immune rejection associated with such allogeneic cell transplantation may hinder their clinical utilization. The human induced pluripotent stem cell technology may provide a potential solution to these challenges, since it generates patient-specific cells that could be coaxed to differentiate into a variety of lineages and subsequently transplanted in an autologous or allogeneic manner.

A flurry of clinical trials using human embryonic stem cells or human induced pluripotent stem cell lineages[6] have focused on the retina (transplantation of retinal pigmented epithelial cells for the treatment of macular degeneration) and other ophthalmologic disorders (retinitis pigmentosa and corneal disorders),[7] on spinal cord injury (using oligodendrocyte progenitors), and on neurodegenerative disorders such as Parkinson disease (using dopaminergic neurons) and amyotrophic lateral sclerosis. Additional targeted disorders include heart failure, pancreatic type 1 diabetes, cartilage defects, and cancer. Early clinical trials indicate that these procedures are safe and well tolerated, but many technical, regulatory, and conceptual challenges remain.

DIRECT REPROGRAMMING. In contrast to approaches involving human induced pluripotent stem cells, which seek to initially reprogram somatic cells into a pluripotent state followed by differentiation into specific cell lineages, direct reprogramming aims to convert the phenotype of one mature cell type directly into another. The prototype for such a strategy was the demonstration that *MyoD*, a master regulator of skeletal muscle formation, can convert

fibroblasts directly to skeletal muscle. Based on the experimental approach used to identify the combination of transcription factors that can reprogram somatic cells into human induced pluripotent stem cells, researchers identified a combination of lineage-specific developmental transcription factors that can convert terminally differentiated fibroblasts or other somatic cells into neuronal cells, β-cells, different hematopoietic cell lineages, and cardiomyocyte-like cells. Despite the unique potential of such strategies, direct reprogramming has not yet reached clinical trials, and in many cases the transdifferentiated cells cannot recapitulate the full extent of the phenotypic properties of the native cells.

Tissue Engineering

Tissue engineering is an interdisciplinary technology that combines principles from life sciences and engineering with the goal of developing functional substitutes for damaged tissues and organs. Regardless of the specific clinical application, tissue-engineering strategies usually involve the utilization of combinations of biomaterials (to generate supporting three-dimensional scaffolds), cells, and biologically active factors. The scaffold serves many purposes, including the control of the shape and size of the engrafted tissue, the delivery of biologic signals and adequate biomechanical support to the cells, the induction of vascularization of the graft, and the protection of the cells from physical damage. Scaffolds used in tissue engineering approaches are commonly divided into two general categories: cellular scaffolds that are seeded ex vivo with cells prior to the in vivo transplantation and acellular scaffolds that depend on cells in the recipient to repopulate the scaffold with subsequent reconstitution. Efforts have mainly concentrated on the musculoskeletal system (bone and cartilage repair) but have also targeted other organs such as the heart and even complex organ structures such as the esophagus, trachea, and urinary bladder. More recently, advances in organ decellularization/recellularization methodologies and three-dimensional bioprinting have allowed the generation of clinically relevant, anatomically accurate engineered tissues and organs.

Specific Disease Applications in Cell Therapy

Although a growing number of experimental cell therapies have reached various stages of clinical trials, as yet none have become established or approved treatments, with the aforementioned exception of hematopoietic stem cells, CAR T cells, and solid organ transplantation. Nonetheless, significant advances may be on the horizon.

NEURODEGENERATIVE DISORDERS. The central nervous system has limited capacity for regenerating lost tissue in both slowly progressive degenerative neurologic conditions (e.g., Parkinson disease, Alzheimer disease, or amyotrophic lateral sclerosis) and in acute injuries that lead to rapid cell loss (e.g., ischemic stroke or traumatic spinal cord injury). Stem cell–based therapies are being explored as potential novel therapeutic paradigms for both acute and chronic neurodegenerative disorders. These procedures could potentially act through the following mechanisms: (1) cell replacement, whereby cells (precommitted to a specific neuronal or glial lineages) are transplanted to replace the specific subtypes of cells that were lost (i.e., dopaminergic neurons in Parkinson disease, motor neurons in amyotrophic lateral sclerosis, or a mixture of different neuronal and glial subtypes in other disorders); (2) trophic support, whereby the engrafted cells are used to promote the survival of affected neurons or glia or stimulate endogenous repair of the diseased brain through the secretion of neurotrophic factors; and (3) modulation of the inflammatory process thought to contribute to the pathogenesis of many neurodegenerative processes.

In Parkinson disease (Chapter 378) cell-replacement therapy suggested significant improvement in motor function after intrastriatal implantation of fetal mesencephalic dopamine-rich tissue obtained from aborted human fetuses aged 6 to 9 weeks. Further progress, however, has been limited by lack of sufficient tissue to treat a large number of affected patients, the variability in functional outcome, reports of serious dyskinesias in a subset of treated patients, and ethical considerations.

Given these limitations, stem cell derivatives could offer a viable alternative by either replacing the dopaminergic neurons or by slowing the degeneration process and restoring the integrity of the nigrostriatal pathway through the release of trophic factors. Preclinical engraftment studies demonstrate that such cells can survive in animal models of Parkinson disease and exert beneficial functional effects following cell maturation. Initial clinical trials using human pluripotent stem cells have begun. The program that has advanced the most has been the transplantation of retinal pigment epithelium derived from human embryonic stem cells and human induced pluripotent stem cells for the treatment of macular degeneration (Chapter 391).

DIABETES MELLITUS. Successful pancreatic transplantation and improved glucocorticoid-free protocols for transplantation of islets of Langerhans can not only restore glucose control in patients with diabetes mellitus but can also prevent or even reverse some of the disease's complications (Chapter 210).[8] However, whole organ or islet-based transplantation approaches are limited both by immunologic rejection and an available source of transplantable tissues. These challenges have motivated the search for cell types that can replace or augment deficient β-cell function.

The differentiation of human embryonic stem cells and human induced pluripotent stem cells into precursor or early-stage β-cells is a potential option. The engraftment of either β-cell progenitors (which are expected to develop and mature in vivo) or more mature β-cells/islet-like tissues can sometimes normalize glucose levels in treated patients.

One of the problems in using β-cells for cell-replacement therapy is that the autoimmune destruction of endogenous β-cells, which underlies the pathogenesis of type 1 diabetes, will probably also result in the destruction of the human induced pluripotent stem cell–derived β-cells. To overcome this challenge, efforts are being made either to genetically manipulate the transplanted cells or to develop encapsulation biotechnologies to deliver the cells in an immunoprotective environment.

Beyond the derivation of new β-cells from pluripotent stem cells, progress has also been made in reprogramming closely related cell types to β-cells by overexpressing master regulatory transcription factors. An additional regenerative strategy focuses on increasing pancreatic β-cell mass by inducing their replication. This therapeutic approach would mainly target type 2 patients with diabetes by decreasing the burden on existing but overworked β-cells.

Finally, several clinical trials have explored the efficacy of mesenchymal stem cells, both as supporting cells to protect existing β-cells and as a source for newly generated β-cells. There is some evidence to suggest that transplantation of mesenchymal stem cells can be effective to a certain degree in type 2 diabetes, but its efficacy in type 1 diabetes is controversial.

STEM CELL–DERIVED PLATFORMS FOR DISEASE MODELING, PERSONALIZED MEDICINE, AND DRUG DISCOVERY. In addition to the generation of cells for regenerative applications, the ability to grow a wide variety of different specialized cell types of human origin in culture (in combination with advances in organ-on-a-chip, tissue engineering, and three-dimensional bioprinting technologies) provides unparalleled opportunities for disease modeling, gene and drug discovery, and drug testing. The advent of human induced pluripotent stem cell technology has further revolutionized this field. Different types of patient-specific human induced pluripotent stem cell–derived neurons, cardiomyocytes, skeletal muscle, blood cells, hepatocytes, and other cell types propagated in cell culture recapitulate disease-relevant phenotypes of a wide array of genetic disorders. Mechanistic insights derived using this approach have enabled predictive testing of existing therapies in a patient-specific manner (personalized medicine) as well as development and preclinical testing of evolving therapies.

GENE THERAPY

Gene therapy can be broadly defined as the transfer of genetic material into cells to restore or correct a cellular dysfunction or to provide a new cellular function in an attempt to cure a disease or to improve the clinical status of a patient. Recent clinical successes include entirely novel initiatives in treating primary immunodeficiency syndromes,[9] blood disorders,[10,11] and leukodystrophies; the improvement of vision in patients with retinal disease[12]; innovative approaches targeting chronic and acute viral infections; and highly encouraging outcomes in treating cancer.[13]

Clinically approved gene therapy agents include fomivirsen for the treatment of cytomegalovirus retinitis, the viral delivery of the lipoprotein lipase (*LPL*) gene for the treatment of LPL deficiency, voretigene neparvovec-rzyl for the treatment of Leber retinal dystrophy, and onasemnogene abeparvovec for the treatment of spinal muscular atrophy. An alternative to the direct in vivo gene delivery approach is the ex vivo genetic engineering of cells that are then engrafted to the patient.[14] The first clinical approval of this strategy involved the ex vivo genetic modification of harvested hematopoietic stem cells to express a functional product of the adenosine deaminases gene for the treatment of severe combined immunodeficiency. A turning point in the field was the development of CAR T cells,[15] which are a genetically modified cellular immunotherapy that can rescue patients who have hematologic malignancies (and recently also certain solid tumors) and who have failed prior conventional therapies.

Classifications and Mechanisms of Action

In general, somatic gene therapy applications can be divided into those aiming to correct or treat genetic disorders and those targeting nongenetic diseases by altering cell, tissue, and organ function. Traditional gene therapy efforts for inherited disorders have mainly focused on the exogenous expression of genes encoding the missing or abnormal proteins. Current and future efforts are expected to shift the focus from uncontrolled overexpression of the missing protein to correcting the mutation at the DNA level (gene editing strategies). For nongenetic disorders, efforts are aimed at overexpressing various proteins in an attempt to alter cellular function (e.g., to increase contractility in heart failure by expressing proteins related to calcium handling), to protect tissue at risk (e.g., in acute kidney injury), to exert paracrine effects through local secretion of specific proteins by the engineered cells (e.g., to promote angiogenesis in ischemic tissues or to induce neurotrophic effects in neurodegenerative disorders), and even to secrete certain proteins and hormones (e.g., to correct bleeding disorders by secreting coagulation factors or to treat anemia by secreting erythropoietin). Finally, major efforts have focused on using gene therapy tools for cancer immunotherapies.

Gene therapy efforts can be divided into ex vivo strategies and direct in vivo strategies. The former involve initial harvesting of cells from a patient, followed by their genetic modification, selection, and amplification in the laboratory, and eventually delivery of the modified cells back to the patient to achieve the desired therapeutic effect. This strategy is attractive for the genetic modification of stem cells or other cell types that could reconstitute relevant tissues and organs following transplantation. Prominent examples include the genetic modification of hematopoietic stem cells for treatment of hematopoietic disorders and various CAR T-cell strategies. Finally, next-generation therapeutic strategies are expected to use genetically engineered cells also to carry drugs and oncolytic viruses to treat intractable tumors and to modulate several tissue processes through the secretion of angiogenic, neurotrophic, and anti-inflammatory molecules.

The in vivo gene therapy approach involves the delivery of the relevant transgene (via different vectors) directly to the targeted tissue. The stable or transient expression of the transgene only in the relevant cells/tissues can be achieved by combining localized delivery, tropism of the vector used to the tissue of interest, and expression of the transgene under the control of a cell/tissue-specific promoter.

Gene Therapy Delivery Methods

Gene therapy agents are often composed of two elements: the genetic material itself (i.e., the DNA expression cassette, short interfering RNA, or an antisense molecule) and the vector delivery system. The latter is often the more complex and limiting component. It is therefore important to tailor the specific vector type for each gene therapy application to allow the most efficient delivery with minimal adverse effects. Vectors used for gene therapy can be classified into nonviral or viral vectors.

Gene therapy mediated by nonviral vectors is referred to as transfection and consists of the direct delivery of naked DNA by injection or in combination with liposomes (cationic lipids mixed with nucleic acids), nanoparticles, and other means. Although nonviral vectors are less toxic and immunogenic and can be produced in large amounts, their efficacy may be transient and insufficient. The efficiency of nonviral vector delivery could be enhanced by different physical methods, such as electroporation (for muscle, skin, and tumors), gene gun (for DNA vaccination), and ultrasound-assisted delivery (for cardiovascular and tumor-related applications).

Gene therapy mediated by viral vectors is referred to as transduction and has become the dominant clinical delivery approach. The idea is to harness the innate ability of viruses to deliver genetic material into the infected cell. Viruses used in gene therapy have been modified to enhance safety, increase specific uptake, and improve efficiency. Viral vectors are derived from viruses with either RNA (retroviruses and lentiviruses) or DNA (adenovirus, adeno-associated virus [AAV], herpes simplex virus [HSV], and poxvirus [vaccine virus]) genomes. Viral vectors can also be integrating, by inserting themselves into the recipient's genome, or nonintegrating, by forming an extrachromosomal genetic element. Integrating vectors, such as gamma-retroviral vectors and lentiviral vectors, are generally used to transfect actively dividing cells. Integrating vectors, however, may carry the risk of insertional mutagenesis, with clinical oncogenic transformations reported for retroviruses. Nonintegrating vectors, such as adenoviral vectors and adeno-associated virus vectors, can be used to transduce quiescent or slowly dividing cells, but they are quickly (in the case of adenoviral vectors) lost from cells that divide rapidly.

Adenoviral vectors and retroviral vectors featured prominently in early gene therapy trials. There has been a movement away from both, however, because of a death that was linked to the toxicity of the adenoviral vector and the leukemic transformation associated with the retroviral vector. These vectors have been replaced with adeno-associated virus and lentiviral vectors. Other viral vectors may be tailored for specific settings. For example, in gene therapies for pain management a replication-defective herpes simplex virus vector is used due to its tropism for nerves, whereas different oncolytic viruses are used in oncology because of their tropism to cancer cells.

Diseases Treated by Gene Therapy

HUMAN STEM CELL–BASED GENE THERAPY. Human stem cells are the preferred target for ex vivo gene therapy since their genetic modification would ensure a steady supply of their gene-corrected progeny in the body. Consequently, such approaches have the potential to treat conditions in which mature hematopoietic lineages fail to develop or to function correctly. The process of hematopoietic stem cell–based gene therapy involves the initial isolation of these progenitors from the bone marrow or peripheral blood using antibodies targeting the CD34 surface marker, followed by ex vivo genetic modification (using lentiviral vectors or gene editing techniques) for expression of the corrective transgene. Before the modified cells are administered back to the patient, the recipient is usually treated with a preconditioning chemotherapy regimen to deplete endogenous progenitors and to favor engraftment of the gene-corrected cells.

Despite the convincing clinical improvement observed in the first-generation human stem cell–based gene therapies for immunodeficiency, the adverse consequences resulting from the random integration of retroviruses have stalled progress in this field for many years. The recent shift to the use of lentiviral vectors and gene editing tools with improved efficacy and safety has renewed interest in the approach. Consequently, human stem cell–based gene therapies have been successfully tested in severe inherited diseases of the immune system (Wiskott-Aldrich syndrome and X-linked severe combined immunodeficiency) and in diseases of the blood (β-thalassemia) and nervous system (adrenoleukodystrophy and metachromatic leukodystrophy).

LIVER. A striking gene therapy success has been to induce the liver to produce coagulation factors for the treatment of coagulopathies, such as hemophilia B (Chapter 160), in which raising circulating coagulation factor levels from <1% (in affected individuals) into the range of 5% may be sufficient for effective treatment.

Cardiovascular disease. The cardiovascular system is emerging as an attractive target for nucleic acid–based therapies.[16] These efforts have focused on novel lipid-lowering approaches, on achieving therapeutic angiogenesis for chronic ischemic heart disease and critical limb ischemia, on improving cardiac function in heart failure, and on correcting monogenic cardiovascular diseases. 16

The use of traditional gene therapy strategies and emerging RNA and genome editing therapies have led to the development of clinical programs for the prevention and management of atherosclerotic cardiovascular diseases by targeting lipid metabolism. These include early-stage clinical trials employing recombinant adeno-associated virus (rAAV)–based liver-directed human LDL receptor (LDLR) gene delivery for the treatment of homozygous familial hypercholesterolemia. The emerging role of RNA-based therapies resulted in development of antisense oligonucleotides or short interfering RNA strategies for lowering apolipoprotein (a), proprotein convertase subtilisin/kexin type 9, *apoCIII*, and *ANGPTL3*. These highly successful lipid-altering strategies have either reached advanced clinical trials or were already approved clinically (i.e., inclisiran, a siRNA-based therapy targeting PCSK9 (Chapter 190).[A1] A1

The use of genes to promote angiogenesis to augment perfusion of the ischemic myocardium or to treat critical limb ischemia has been the focus of two decades of preclinical research using a variety of angiogenic mediators. Overall, these gene therapy approaches were very successful in various animal models, but human trials provided inconsistent results. Another important gene therapy target has been heart failure and various cardiomyopathies. One effort that reached advanced clinical trials was the expression of the sarcoplasmic reticulum calcium ATPase (SERCA2a), which led to the restoration of abnormal calcium transients and improved cardiac contractility in animal models with heart failure. However, human trials failed to demonstrate clinical benefits, most probably due to inefficient myocardial transgene expression. Nevertheless, efforts focusing on additional targets are ongoing.

CANCER (SEE ALSO CHAPTER 164). One of the most exciting opportunities for gene therapy lies in the cancer arena. Gene therapy strategies targeting cancer include the use of naturally occurring or modified viruses to induce

cytotoxic or growth inhibitory effects in cancer cells, gene therapies to boost the immune response to tumor antigens, and mRNA antitumor vaccines.

Antitumor cytotoxicity and growth inhibition. Oncolytic viruses are therapeutically useful anticancer viruses that preferentially infect and damage malignant tissues without causing harm to normal tissues. Cancer selectivity takes advantage of deficiencies characterizing many tumor types, such as deficient innate antiviral response mechanisms, susceptibility to cell injury pathways (e.g., reactive oxygen species), deficient tumor suppressors, and restoration of defective cell death pathways such as apoptosis. Several viruses such as the Newcastle disease virus (which activates the innate or adaptive immune response), reovirus (which activates host protein kinases to shut down protein production), and mumps virus preferentially target cancer cells, thereby causing cell death and tumor regression. Other oncolytic viruses include modified versions of Coxsackie, herpes, vaccinia, adeno, rhabdo, and measles viruses.

Although the foregoing approaches have inherent anticancer activity, viruses such as vesicular stomatitis poliovirus can be genetically engineered to engender oncolytic activity. Beyond the direct viral cytopathic effect, viral vectors can be engineered to deliver genes to cancer cells that will result in tumor cell death. Tumor cell selectivity for activation of such genes can be achieved using promoters that are activated only in cancer cells (e.g., human telomerase or survivin) or in specific types of tumors (e.g., probasin in prostate cancer, ceruloplasmin in ovarian cancer, or HER2 in breast cancer). Suicide gene therapy involves delivery of a pro-drug activating enzyme (suicide gene) that converts nontoxic pro-drugs to cytotoxic metabolites.

Oncorine, which is a recombinant oncolytic virus that selectively replicates in p53-deficient tumors, is used in China for patients with squamous head and neck or esophageal cancer. Talimogene laherparepvec is a recombinant human herpes simplex virus modified to optimize local spread and elaboration of human granulocyte-macrophage colony stimulating factor. This agent is an oncolytic virus approved by the FDA for the treatment of locally advanced or metastatic cutaneous melanoma and is under study for the treatment of hepatocellular, pancreatic, and other solid tumors.

Gene therapies aiming to boost the immune response to tumor antigens. Immunotherapeutic approaches are rapidly emerging as the "fifth pillar" (along with surgery, radiation, chemotherapy, and growth factor pathway–targeted therapies) in the treatment of cancer. Among these approaches, CAR T-cell anticancer therapy can be considered a form of combined gene and cell therapy. The approach is based upon ex vivo genetic engineering of T cells from the cancer patient (Fig. 34-5). CAR T-cell therapy requires drawing blood from the patient, separating the T cells, and genetically engineering the T cells ex vivo to express surface CARs and then expanding them in vitro. CARs are synthetic molecules which enable the engineered T cells to recognize and attach to a specific protein, or antigen, on tumor cells. Following a prior chemotherapy immunodepletion step, the CAR T cells are infused into the patient. Infused CAR T cells multiply in the patient, where they target, attack, and kill cells expressing the surface antigen corresponding to the genetically engineered CAR. This process may elicit an extensive massive cytokine release response, which is an "on-target" adverse effect, whose clinical management using corticosteroids and anti–interleukin-6 drugs, along with the treatment of other adverse effects (e.g., neurotoxicity), is a *sine qua non* for the overall success of this novel anticancer therapy approach.

The CAR T-cell therapies, which have been extensively studied and approved for clinical use, target the CD19 surface antigen on B cells and are effective for B-cell malignancies, including childhood acute lymphocytic leukemia and diffuse B-cell lymphomas. The remarkable success of CAR T-cell therapy to achieve durable remissions, even in relapsed or poor prognosis disease, has now led to the successful extension of CAR T-cell therapy targeting the CD22 and CD123 antigens in leukemias and the BCMA protein in myeloma.[A2] A2

RNA-Based Therapeutics

Recent advances in the generation, purification, and cellular delivery of RNA have allowed the development of several types of RNA-based therapeutics.[17] 17 These diverse RNA-based therapies include approaches that (1) inhibit protein generation by promoting RNA degradation and/or inhibition of protein translation (antisense oligonucleotides, small interfering RNAs, or microRNAs); (2) bind receptors and inhibit signal transduction (aptamers); or (3) induce protein expression (mRNA therapeutics) (Fig. 34-6).

Antisense Oligonucleotide, Small Interfering RNAs, and microRNAs

ANTISENSE OLIGONUCLEOTIDES. Antisense oligonucleotides are short, single-stranded oligonucleotides that can pair with complementary sequences in endogenous messenger RNA (mRNA) transcripts, thereby altering their processing and eventually affecting specific protein translation (Fig. 34-6).[18] 18 By binding to their targets, antisense oligonucleotides can modulate the splicing of pre-mRNAs (allowing skipping or inclusion of a targeted exon), induce the degradation of target mRNAs (by the RNase H-mediated degradation process), or block the translation of mRNAs into proteins (by steric hindrance of ribosomal activity).

Several antisense oligonucleotide drugs have already received clinical approval, and several others are in advanced clinical trials, Eteplirsen is a representative of a group of morpholino-oligos approved to treat Duchenne muscular dystrophy (Chapter 389), which is caused by mutations that produce a premature stop codon and a nonfunctional dystrophin protein (most commonly in exon 51 of the *DMD* gene). Eteplirsen recognizes and hybridizes to exon 51 of the dystrophin gene, thereby modulating the pre–messenger RNA splicing process to exclude exon 51 from the mature mRNA. This process restores the reading frame and leads to translation of a shortened, but functional, dystrophin protein. Similarly, nusinersen is used to treat spinal muscular atrophy (Chapter 387) by binding to the *SMN2* gene pre-mRNA, thereby inducing the inclusion of exon 7 and, consequently, the stability of the translated protein as an alternative to the mutated SMN1 protein.[A3] Mipomersen induces the degradation of A3
apolipoprotein B mRNAs to treat familial hypercholesterolemia (Chapter 190), whereas inotersen is used to treat familial amyloid polyneuropathy (Chapter 174) caused by the mutations in the transthyretin (*TTR*) gene.[A4] A4

SMALL INTERFERING RNA (siRNA). RNA interference (RNAi) regulates gene expression through a highly precise mechanism of sequence-directed gene silencing by specific mRNA degradation. Whereas the antisense oligonucleotide techniques are based on single-stranded RNA, the molecule utilized in the RNAi pathway is small interfering RNA (siRNA), a short-sized,

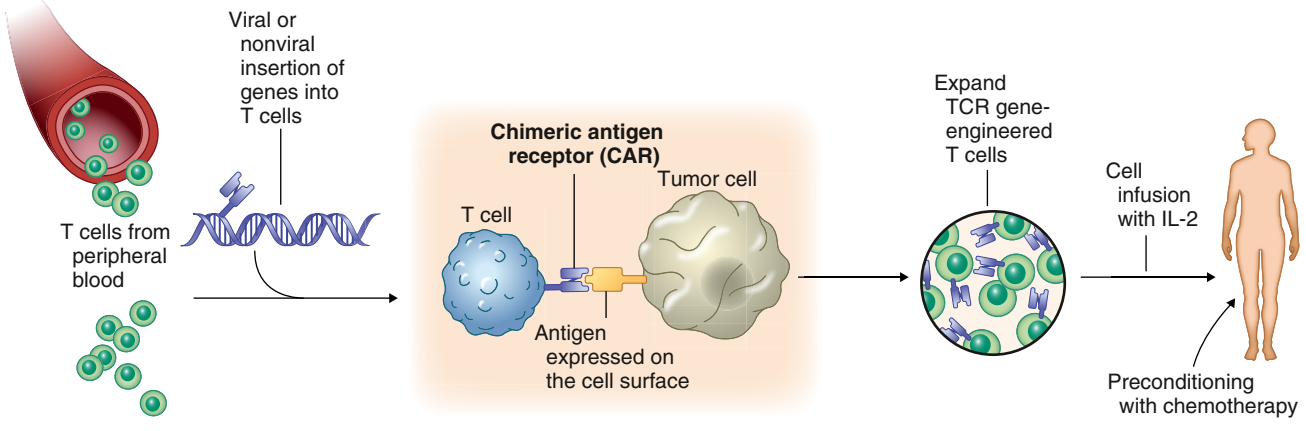

FIGURE 34-5. CAR T-cell anticancer therapy. CAR T cells are genetically engineered ex vivo to produce chimeric antigen receptors (CARs) on their surfaces. They are then expanded in the laboratory and reinfused into the patient. IL = interleukin; TCR = T-cell receptor. (Adapted from National Cancer Institute publication at https://www.cancer.gov/about-cancer/treatment/research/car-t-cells. Credit: National Cancer Institute.)

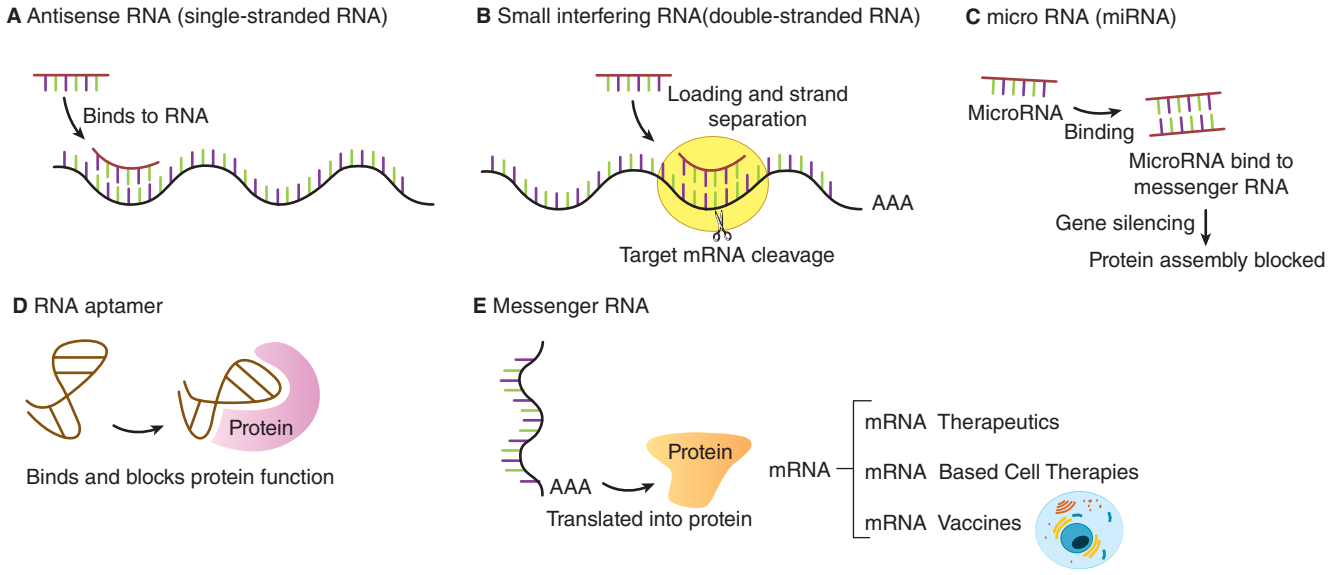

FIGURE 34-6. RNA therapies. A, Antisense RNA. The single-stranded antisense RNA hybridizes to the target mRNA. After binding, it modulates the splicing of pre-mRNA and/or induces the degradation of mRNA and/or inhibits the translation of mRNA into protein. **B,** Small interfering RNA (siRNA). siRNAs are short (20 to 25 nucleotides), double-stranded RNA molecules that use the RNAi pathway to degrade a target mRNA in a sequence-specific manner. After loading into the RNA-induced silencing complex (RISC), one strand is removed after strand separation. The guide strand then guides the RISC to the target mRNA, which is recognized and cleaved. **C,** microRNA (miRNA). miRNAs are small, noncoding RNA molecules that regulate the expression of multiple mRNAs by blocking translation or promoting degradation of the target mRNAs. **D,** RNA aptamers. The RNA aptamer can bind to a specific protein and block its function. **E,** Synthetic messenger RNA. After the messenger RNA (mRNA) is introduced into the cells, cellular machinery, including the ribosome, translates its information into a protein, the final product that can work as an enzyme or antigen. The mRNA-based therapies can be divided into three conceptual groups: (1) replacement therapy (mRNA therapeutics), (2) mRNA-based vaccines, and (3) mRNA-based cell therapy. mRNA = messenger RNA.

double-stranded RNA (Fig. 34-6). After being loaded into the cell's RNA-induced silencing complex (RISC), the double strands of siRNA are separated and one strand is discarded. The remaining RNA strand binds to the target mRNA sequence specifically, and the RISC machinery induces its degradation.

The use of RNAi for therapeutic applications is based on repressing the function of proteins implicated in several disease states such as cancer, age-related macular degeneration, and amyloidosis. In addition, siRNA-based, allele-specific silencing (resulting in reduced expression of the mutated "toxic" allele) can be used to target a variety of dominant-negative genetic disorders, such as Huntington disease (Chapter 379).

Currently, several siRNA-based therapeutics received FDA approval. The first approved siRNA drug, patisiran, exerts its effect by targeting the 3' untranslated region of transthyretin mRNA in the liver. By suppressing the expression of TTR, patisiran can prevent the systemic deposition of amyloid aggregates and is indicated to treat adult patients with polyneuropathy due to hereditary TTR amyloidosis (Chapter 174).[A5] Givosiran, which is intended to treat acute hepatic porphyria (Chapter 194),[A6] targets aminolevulinate synthase 1 mRNA in the liver and reduces the levels of the disease-causing neurotoxic intermediate proteins. Inclisiran binds to and cleaves the mRNA sequence of proprotein convertase subtilisin/kexin type 9 (PCSK9), thereby interfering with LDL receptor recycling in the liver and reducing LDL levels for more than 6 months (Chapter 190). Similarly, olpasiran was shown to reduce the levels of lipoprotein(a), another cardiovascular risk factor.[A7] Lumasiran, which targets glycolate oxidase,[19] reduces hepatic oxalate production for the treatment of primary hyperoxaluria type 1 (Chapter 189).

MICRORNA (MIRNA) MIMICS AND INHIBITORS. MicroRNAs are small, noncoding RNA molecules that regulate the expression of multiple mRNAs by blocking their translation or inducing their degradation. The miRNA-based therapeutics can be categorized into miRNA mimics and miRNA inhibitors (Fig. 34-6). The former are double-stranded RNA molecules that mimic the function of endogenous miRNAs, whereas the latter are single-stranded RNA oligos designed to interfere with specific endogenous miRNAs. Although no miRNA-based drugs are currently approved, promising candidates in clinical trials include miRNA inhibitors targeting specific miRNAs thought to play a role in hematologic malignancies, in solid tumors such as glioblastoma multiforme, in chronic hepatitis C, and in tissue repair. Potential therapeutic targets of miRNA mimics include keloid and pathologic fibrosis as well as modulation of the tumor microenvironment of different solid cancers.

APTAMERS. Aptamers are short, single-stranded nucleic acids that can bind to a variety of proteins, peptides, carbohydrates, and other molecules by virtue of their tertiary structure (Fig. 34-6). Consequently, aptamers can serve as agonists, antagonists, bispecific activity, and even carriers for other drugs. In this regard, aptamers have the potential to replace monoclonal antibody–based therapies. Pegaptanib, the first RNA aptamer drug, was developed to treat the wet type of age-related macular degeneration (Chapter 391). It acts by binding to vascular endothelial growth factor (VEGF), thereby preventing the formation of abnormal and leaky blood vessels. Other aptamers are currently in clinical trials for indications ranging from diabetic nephropathy, to multiple type of cancers (lung, pancreatic, and glioblastoma), to coagulation disorders.

MESSENGER RNA-BASED THERAPEUTICS. mRNAs serve as the intermediates between the coding genomic DNA and the encoded proteins. Synthetic mRNA is engineered to mimic naturally occurring mRNA, so as to prevent it from being recognized as foreign biologic material and being destroyed by the immune system. One of the most advanced approaches is to encase the mRNA in lipid nanoparticles. However, the activity of synthetic mRNAs is still transient, ranging from days to weeks.

Replacement therapy. In replacement therapy, modified RNA is administered to replace or compensate for a defective gene or protein or to supply therapeutic proteins. Many rare genetic diseases can be targeted using this approach. In cystic fibrosis (Chapter 77), for example, the mRNA encoding CFTR, a chloride channel that is defective in this disease, is delivered to lung epithelial cells by nebulization. Other mRNA-based therapeutic applications are being developed for different metabolic, infectious, and cardiac diseases. The largest number of mRNA-based applications are in the cancer arena, focusing mainly on immuno-oncology applications.

mRNA-based vaccines. Synthetic mRNAs encoding specific antigens can be used for vaccination to induce immunity against infections (prophylactic vaccines) or to harness the immune system to fight specific cancer types (therapeutic vaccines). For the former, the SARS-CoV-2 pandemic revealed the potential of the modified RNA technology for prophylactic vaccination (Chapter 337).[A8,A9]

MRNA ANTI-TUMOR VACCINES. Once in the body, the delivered mRNA directs cells that take up the mRNA (such as dendritic cells) to produce proteins that may stimulate an immune response against targeted proteins present in tumor cells. After taking up and translating the mRNA, dendritic cells present the resulting proteins, or antigens, to immune cells such as T cells, thereby starting the immune response. As in the case of CAR T-cell therapy, personalizing the vaccine for the antigens relevant to a given patient tumor, or developing banks for vaccines relevant to characterized tumor neo-antigens, are likely to be the future manner in which antitumor mRNA vaccines join in the repertoire of gene and cell therapy for malignant disease.

Cell therapy. Cell therapy may be enhanced by the mRNA approach by generation of engineered cells with unique properties tailored for specific applications. The cells may be obtained in an autologous manner, from pluripotent stem cells, or from a cell bank. Subsequently, candidate cells are therapeutically modified ex vivo with mRNA encoding the desired proteins (such as CARs or reprogramming or transdifferentiation factors) and delivered to the patient. In contrast to genetically modified cells with DNA plasmids, the effects achieved by mRNA expression are temporary.

GENOME EDITING

The center of gravity for gene therapy may be shifting from the addition of a therapeutic gene by conventional gene therapy strategies to genome editing, whereby a pathogenic mutation can be corrected at its natural location in the genome using programmable nucleases. Such programmable nucleases include zinc-finger nucleases (ZFNs), transcription activator-like effector nucleases (TALENs), and the more recently described clustered regularly interspaced
20 short palindromic repeat associated nuclease Cas9 (CRISPR-Cas9).[20] These genome-editing methodologies can be used not only to correct mutations but also to inactivate (or knock out) deleterious mutations in diseased cells, to disrupt viral DNA, and to add therapeutic transgenes. Such genome-editing therapies have already entered advanced preclinical and clinical testing for a
21 variety of indications.[21]

Genome Editing Mechanisms of Action

Programmable nucleases act as highly specific molecular scissors engineered to target a specific sequence in the genome and introduce a double-strand break in the DNA just proximal to the targeted site (Fig. 34-7). The predominant cellular pathway to repair double-stranded DNA breaks is nonhomologous end-joining, which joins two double-stranded break ends by direct ligation with no or little homology between the joined ends. As a result, nonhomologous end-joining is associated with a high probability for error by resulting in the insertion or deletion of a few nucleotides at the break site. The resulting insertion-deletion (*indel*) mutations can therefore be exploited to selectively inactivate genes (Fig. 34-7A) and specifically genes that are responsible for the abnormal clinical phenotype.

The same logic can also be extended to protect against infectious or genetic diseases by inactivating wild-type genes that favor the pathologic processes. Examples include inducing loss-of-function mutations in the CCR5 T-cell receptor to treat HIV infection, in the *PCSK9* gene to treat hypercholesterolemia, and in the *TTR* gene to treat ATTR amyloidosis-related polyneuropathy.[22] The first approved gene editing clinical trial involved the use of 22
zinc finger nucleases to target the *CCR5* locus in autologous CD4+ T cells ex vivo by adenoviral vectors for the treatment of HIV infection. Clinical follow-up revealed that the transfer of the gene-edited T cells into patients was well tolerated and that the *CCR5*-knockout cells were protected to a certain extent from infection with CCR5-tropic HIV. Similarly, programmable nucleases may also be used to target foreign DNA, such as viral genomes, thereby specifically targeting and inactivating viral-specific genes without affecting host human-specific DNA. Such an approach is in clinical trials targeting human papilloma virus (HPV). Finally, targeting of two nucleases to make two double-stranded breaks around an insertion (Fig. 34-7B) may be useful for treatment of nucleotide expansion disorders such as spino-cerebellar ataxia and Huntington disease.

An alternative mechanism to resolve the DNA cleavage is by homology directed repair between the endogenous DNA and an exogenously introduced donor fragment containing the normal nucleotide sequence (Fig. 34-7C). In this fashion, the pathogenic mutation is permanently corrected back to the normal sequence. This mutation correction approach preserves the architecture of the genome and maintains gene control under the normal cellular regulatory elements and could therefore be used to target a wide array of genetic disorders.

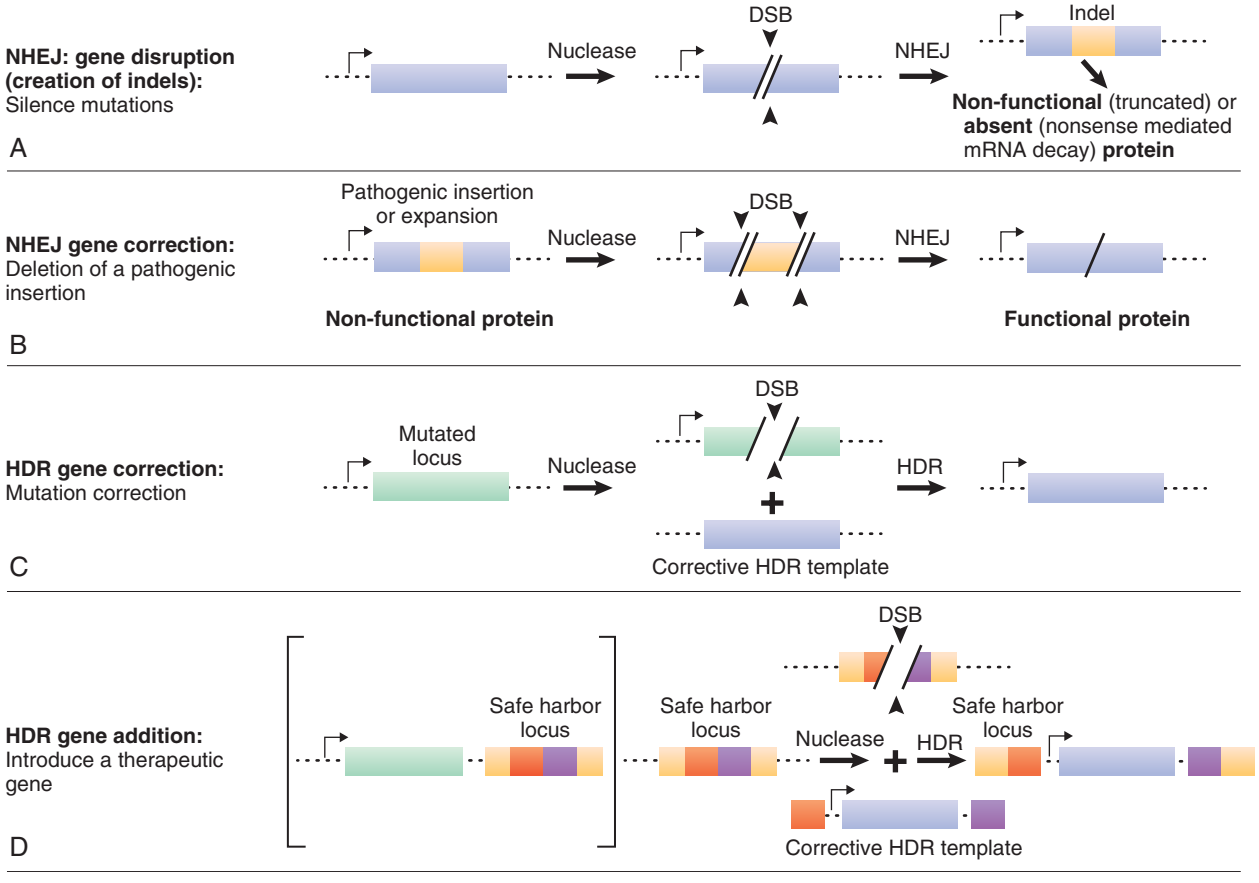

FIGURE 34-7. Conceptual therapeutic genome-editing modifications. The specific type of genome-editing therapeutic strategy depends on the nature of the mutation/disease. **A,** Nonhomologous end-joining (NHEJ) gene disruption. For gene disruption, expression of the pathologic protein is suppressed by introducing a double-stranded break (DSB) at the desired gene locus. The ineffective endogenous NHEJ repair mechanism leads to formation of indels in the gene of interest, often resulting in frameshift mutations that create premature stop codons and a nonfunctional protein product (truncated protein) or nonsense mediated decay of transcripts (no protein). **B,** NHEJ gene correction. Two DSBs targeted to both sides of a pathogenic expansion or insertion may be resolved by NHEJ, causing a deletion of the intervening sequences to mediate therapy. **C,** Homology directed repair (HDR) gene correction. For mutation correction, the HDR gene correction mechanism is used. A DSB is induced near the mutation site. HDR repair of the break site is achieved with an exogenous template, correcting the mutation and restoring normal gene function. **D,** Gene editing. This approach introduces a therapeutic transgene into either the native or a non-native (safe harbor site) locus in the genome. A DSB is induced at the desired locus, and an HDR template containing the relevant transgene and associated transcription control elements is introduced to the nucleus. mRNA = messenger RNA.

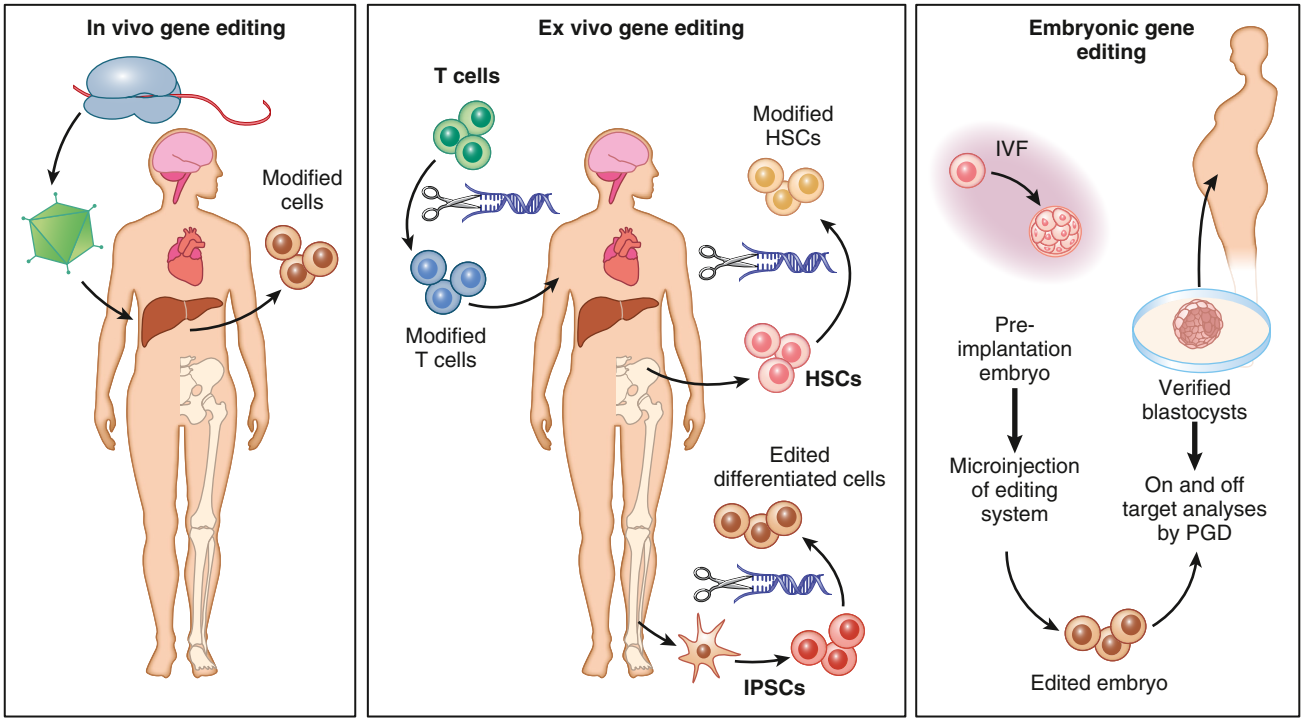

FIGURE 34-8. Ex vivo versus in vivo therapeutic genome therapy strategies. In ex vivo editing therapy, cells are removed from a patient, undergo genome editing, are expanded, and are then engrafted back to the patient to repopulate the diseased organ/tissues with healthy cells. Unique candidates for such an approach are HSCs, which can then be reintroduced by bone marrow transplantation. Alternative candidates are patient-specific iPSCs, which can be generated from a diseased individual, genetically modified, coaxed to differentiate into the desired cell lineage (e.g., heart cell, nerve cells, liver cells) and then transplanted back to the same patients. In vivo therapy involves genome editing of cells in situ. Delivery could be systemic or localized, with the preferred candidate organs being the liver, muscle, brain, and eye. For embryonic correction, the early-stage embryo formed during in vitro fertilization can undergo gene editing, and the corrected blastocyst can then be returned to the mother. HSCs = hematopoietic stem cells; iPSCs = induced pluripotent stem cells; IVF = in vitro fertilization; PGD = preimplantation diagnosis.

Finally, site-specific nucleases may also bring a unique value by enabling insertion of therapeutic transgenes (Fig. 34-7D) into specific safe harbor locations in the human genome, thereby ensuring long-term expression of the transgene, achieving better control over transgene copy number and expression levels, and reducing the potential for random insertional mutagenesis. Gene insertion may be used to secrete certain factors or to favorably alter the phenotype of the genetically modified cell.

The aforementioned strategies for gene modifications can be utilized either via a direct in vivo approach to modify existing cells (e.g., targeting liver cells) or alternatively by an initial ex vivo cell modification step followed by in vivo transplantation of genetically modified cells (Fig. 34-8).

The first clinical trials involving CRISPR/Cas9 in China and later in the United States involved the ex vivo disruption of the programmed death 1 (PD-1) gene in extracted T cells, which were then reinjected into the patients to generate more efficacious cancer immunotherapies to treat multiple myeloma, pancreatic and lung cancer, or glioblastoma. More than 100 ongoing clinical trials of CRISPR/Cas gene editing and other gene editing technologies in different disease types have confirmed the safety and feasibility of the technique for human gene therapy. These trials focus primarily on five clinical fields: blood disorders, cancer, ophthalmologic disorders, chronic infections, and protein-folding disorders.

Efforts in treating blood disorders have focused on development of CRISPR-based treatments of sickle cell anemia (Chapter 149) and β-thalassemia (Chapter 148).[23] Both hemoglobinopathies could theoretically be cured by isolating hematopoietic stem cells from the patients and using genome editing to either correct the disease-causing mutation in β-globin or to activate the expression of γ-globin, a fetal form of hemoglobin that could substitute for defective β-globin. The edited stem cells are then transplanted back into the patient. All patients treated so far showed normal or near-normal hemoglobin levels. The challenge for these approaches will be to achieve efficient, robust, and specific gene modification of the ex vivo hematopoietic stem cells since they cannot undergo effective clonal expansion. CRISPR/Cas9 may also be used to improve cell-based immunotherapies such as next-generation CAR T cells, which are safer, more controllable, and more efficacious.

In cases in which somatic approaches do not look promising, researchers are considering a third approach by making permanent changes to the genomes of human embryos. From a medical perspective, this approach has the advantage that gene correction will be permanent, so neither the treated person nor any of their descendants will carry the disease allele. In principle, the procedure would involve manipulating embryos at a very early stage, in conjunction with in vitro fertilization (Fig. 34-8). In a proof-of-concept study, a genetic mutation in the *MYBPC3* gene (causing hypertrophic cardiomyopathy) was corrected in viable preimplantation human embryos. In this and other studies, the embryos were never implanted, but the feasibility of this controversial approach was demonstrated.

35 THE INNATE AND ADAPTIVE IMMUNE SYSTEMS

MARY K. CROW

THE IMMUNE SYSTEM IN HOST DEFENSE

The immune system, comprising cells, the molecules they produce, and the organs that organize those components, evolved over millions of years in response to infections with pathogenic microorganisms. Its essential role in maintaining health is based on recognition and elimination or control of those foreign microbes. Central to its efficacy is its capacity to distinguish foreign and dangerous invaders from self-components.[1] In addition to host defense, the immune system is involved in the prevention of malignancy by surveying and recognizing self-cells that express novel antigens,[2] as well as in resolution and repair of tissue damage.

The immune system is described as including an *innate immune system* and an *adaptive immune system*. The former provides the first and rapid line of defense to a foreign stimulus.[3] The latter, dependent on activation by cells of the innate immune system, develops a more specific response targeted to the offending organism and generates memory for that stimulus that can be elicited rapidly should that organism be encountered on a later occasion.[4]

Immune system cells derive from precursor cells of the hematopoietic lineage in the bone marrow (Chapter 142) and populate discrete lymphoid organs, including lymph nodes, spleen, and thymus, as well as skin and intestine. Cells of the innate immune system serve as sentinels at locations that are likely to encounter foreign organisms, and after activation they often travel to a local lymphoid organ. The induction of the adaptive immune response occurs in the context of structured aggregates of innate and adaptive immune cells in the lymphoid organs. Once activated and differentiated to produce effector molecules, immune system cells can be sampled in blood as they travel to sites of infection or tissue damage. There they interact directly with target cells to mediate cell death. Alternatively, they provide activating signals to expand or regulate a response or secrete high local levels of immunomodulatory proteins called cytokines. Cytokines communicate among cells within the immune system or between immune system cells and cells in other tissues.[5]

Important advances in characterization of the cell surface and intracellular pattern recognition receptors, particularly the Toll-like receptor (TLR) family and signaling pathways used by innate immune cells to implement a defensive response, are now understood to have relative specificity for pathogen-associated molecular patterns that are characteristic of categories of microbes.[6] In contrast to those receptor systems that initiate an innate immune response, the protein products that implement the response, whether to expand the reaction, promote cell trafficking to the most relevant location, or shape the differentiation programs of adaptive immune system cells, do not show specificity based on the initial triggering stimulus. The products of the innate immune system can be highly effective at ablating or limiting the extent of infection and can generate a tissue repair program that establishes a satisfactory resolution of the episode of infection.

In contrast to recognition of structural patterns common in the microbial world by cells of the innate immune system, the adaptive immune system is designed to respond to the entire continuum of antigens.[7] This goal is achieved through two principal types of antigen recognition receptors: T-cell receptors and antibodies. α/β T-cell receptors, which are the most abundant class of T-cell receptors, interact specifically with epitopes formed by a small linear peptide embedded in major histocompatibility complex (MHC) molecules on the surface of antigen-presenting cells. Antibodies, or immunoglobulins, are expressed as cell surface receptors on B cells or are secreted, with both having the same specificity for antigen by recognizing conformational structures formed by the tertiary configuration of proteins.

The cells and products of the immune system function as an exquisitely regulated complex system. Inherited variations in hundreds of genes have evolved, under pressure of microbial challenge, to ensure adequate defense against pathogenic organisms across the human population. However, in any one individual, the composite genetic profile can generate vulnerability to infection or, alternatively, autoimmune or inflammatory disease.

CELLULAR ELEMENTS OF THE INNATE IMMUNE SYSTEM

Monocytes and Macrophages

Monocytes circulate in the peripheral blood with a half-life of 1 to 3 days. Macrophages arise from circulating patrolling monocytes that have migrated out of the circulation and have proliferated and differentiated in tissue. Tissue-resident macrophages may represent a separate yolk sac–derived cell lineage, with their differentiation influenced by tissue-specific factors, and include alveolar macrophages in the lung, Kupffer cells in the liver, osteoclasts in bone, microglia in the central nervous system, and type A synoviocytes in the synovial membrane.[8] Macrophages secrete myriad products, including hydrolytic enzymes, reactive oxygen species, cytokines, and chemokines. Macrophages engulf microorganisms and foreign particles directly and can be activated by protein complexes containing antibodies that bind to cell surface receptors for the Fc portion of immunoglobulin molecules (Fc receptors, or FcRs). These encounters activate intracellular signaling pathways that induce transcription of target genes, primarily those encoding mediators that promote inflammation or enzyme-mediated death of the microbe. Cytokines from other immune system cells, including interferon (IFN)-γ or interleukin (IL)-4, can drive macrophage differentiation toward the production of mediators that are primarily pro-inflammatory or to a wound healing functional profile. Researchers have characterized those functional phenotypes as M1 or M2, although it is recognized that the context of an innate immune response will determine the functional response, with composite profiles common. In addition to responding to foreign microbes,[9] macrophages contribute to the elimination of senescent or apoptotic cells through a process called efferocytosis and in a manner that avoids induction of an inflammatory response.[10] Macrophages also interact with other cell types through complementary cell surface adhesion or costimulatory receptors. After capturing antigen, they can function as antigen-presenting cells for T lymphocytes, and they can interact with non–immune system cells such as endothelial cells or fibroblasts.

Dendritic Cells

Dendritic cells comprise a complex family of cells that perform essential functions in the innate immune response and serve as a bridge to activation of an adaptive immune response. Myeloid dendritic cells incorporate antigens derived from invading microbes, travel to nearby lymph nodes, and present processed antigenic peptides to T cells in the form of peptide–MHC molecule complexes. They are the most effective antigen-presenting cells[11] based on expression of cell surface costimulatory molecules, and they produce cytokines, including IL-12 and IL-23, after interaction with pathogen-associated molecular patterns (PAMPs). They thereby contribute to the shaping of the T-cell differentiation program to generate effector cell functions. Plasmacytoid dendritic cells are highly efficient producers of type I IFN, a key mediator of host defense against viral infections, after interaction of nucleic acids with their endosomal Toll-like receptors.

Natural Killer Cells

Natural killer (NK) and NK T cells provide early defense against viral infections and other intracellular pathogens while adaptive responses are developing. NK cells are sensitized by cytokines, including type I IFNs, released from plasmacytoid dendritic cells and macrophages, and secrete abundant IFN-γ, which activates macrophages and other cells. They also are poised to kill virus-infected cells by injecting pore-forming enzymes and granzymes. Activation of NK cells is inhibited by interaction with self-MHC class I molecules on target cells. When those self-histocompatibility antigens are not present, NK cell–mediated killing is implemented. NK cells are important in tumor surveillance because they are able to kill MHC class I–deficient tumor cells that are no longer susceptible to adaptive immune responses. In addition to NK cells, innate lymphoid cells, a type of lymphocyte that participates early in innate immune responses but does not express rearranged receptors, are a focus of current study and are particularly important in immune responses in the gut.[12]

Neutrophils

Neutrophils are the most abundant circulating white blood cells. They are recruited rapidly to inflammatory sites and can phagocytose and digest microbes (Chapter 153). Activation of neutrophils and phagocytosis is facilitated through the triggering of FcRs or complement receptors. Microbe-containing phagosomes fuse with lysosomes, which contain enzymes, proteins, and peptides that inactivate and digest microbes. Beyond their phagocytic capability, neutrophils produce a variety of toxic products in the respiratory burst, which

ABSTRACT

The innate immune system provides a fast-acting first line of defense in response to a foreign insult. Cells of the innate immune system serve as sentinels at locations that are likely to encounter foreign organisms, recognize structural patterns common in the microbial world, and implement a defensive response to those microbes. After the initial response they provide a bridge toward activation of the adaptive immune response. The products of the innate immune response can be highly effective at limiting the extent of infection and can generate a tissue repair program that resolves the episode. However, for most infections the adaptive immune system is required to ensure effective host defense and the generation of immune memory. The adaptive immune system expands the repertoire and effectiveness of the immune response through T-cell receptor recognition of linear peptides associated with major histocompatibility molecules on antigen-presenting cells, and recognition of conformational structures of proteins by immunoglobulins expressed on the surface of B cells or secreted. Together, the innate and adaptive immune systems can restore homeostasis after a microbial challenge, but when their response is sustained or poorly regulated, they can mediate autoimmune and inflammatory diseases.

is a process accompanied by an increase in oxygen consumption. During the respiratory burst, oxygen radicals are generated by nicotinamide adenine dinucleotide phosphate (NADPH) oxidases. Neutrophils also contribute to host defense through extrusion of DNA and associated proteins in the form of neutrophil extracellular traps to which bacteria can stick, facilitating their clearance. Despite their effective contributions to the innate immune response and microbial host defense, neutrophils can generate considerable collateral damage. Neutrophil extracellular traps have the capacity to induce production of cytokines by plasmacytoid dendritic cells and may damage vascular endothelial cells.[13] Secretion of neutrophil granule contents, particularly their enzymes (myeloperoxidase, elastase, collagenase, and lysozyme), causes direct cellular injury and damages macromolecules at inflamed sites.

Eosinophils

In contrast to macrophages and neutrophils, eosinophils are only weakly phagocytic but are potent cytotoxic effector cells against parasites. Their major effector mechanism is the secretion of cationic proteins (major basic protein, eosinophil cationic protein, and eosinophil-derived neurotoxin). These proteins are released into the extracellular space, where they directly destroy the invading microorganism but can also damage host tissue (Chapter 156).

Basophils and Mast Cells

Basophils and tissue mast cells secrete inflammatory mediators such as histamine, prostaglandins, leukotrienes, and some cytokines. Release of these substances is triggered when cell surface immunoglobulin E (IgE) receptors encounter monomeric IgE. They play a role in atopic allergies, in which allergens bind immunoglobulin (IgE) and cross-link FcεRs. Mast cells have been observed in rheumatoid arthritis synovial tissue and have been implicated in local inflammatory responses (Chapter 235). Like plasmacytoid dendritic cells and macrophages, mast cells express Toll-like receptors and FcRs and produce cytokines after encountering immune complexes composed of Toll-like receptor ligands.

PRINCIPLES OF INNATE IMMUNE SYSTEM ACTIVATION: RECOGNITION OF IMMUNE STIMULI AND GENERATION OF EFFECTOR FUNCTION

Recognition Receptors and Triggers of an Innate Immune Response

Toll-like Receptors

The innate immune system uses both cell surface and intracellular pattern recognition receptors to recognize conserved structures on microbes (PAMPs). Examples of PAMPs are bacterial lipopolysaccharides, peptidoglycans, mannans, bacterial DNA, double-stranded RNA, and glucans. The discovery and characterization of the Toll-like receptor (TLR) family of receptors and their relevant ligands have focused attention on the mechanisms that allow an innate immune response to shape the nature of the resulting inflammatory or repair programs, as well as the T-cell effector functions that follow recognition of antigens from the relevant pathogen. The Toll-like receptors have in common leucine-rich domains and bind PAMPs common to classes of pathogenic organisms. For example, TLR-4, a cell surface–expressed pattern recognition receptor, binds lipopolysaccharide of gram-negative bacteria, and TLR-2 recognizes bacterial peptidoglycans and lipoproteins, often based on dimerization with other Toll-like receptor family members. Important advances in understanding systemic autoimmune diseases have followed the characterization of endosomal Toll-like receptors with relative specificity for single-stranded RNA (TLR-7 and TLR-8), demethylated 5′-cytosine-phosphate-guanine-3′ (CpG)-enriched DNA (TLR-9), and double-stranded RNA (TLR-3, which has both cell surface and endosomal forms). The distribution of particular Toll-like receptors among cells of the innate immune system varies, contributing to the distinct roles played by those cells in immune responses. The Toll-like receptors alert the immune system that a microbe, typically a bacterium in the case of TLR-2 and TLR-4 or a virus in the case of TLR-3, TLR-7, TLR-8, and TLR-9, is threatening the host. But in some cases, when an immune complex with self-nucleic acid gains access to an endosomal Toll-like receptor, a self-directed innate immune response can be initiated or amplified.[14]

Cytoplasmic Nucleic Acid Sensors

Following the description of the Toll-like receptor family and their capacity to recognize microbial and self-nucleic acids, a second category of intracellular innate immune system receptors was defined that recognize RNA or DNA from microbes, primarily viruses, that gain access to the cell cytoplasm. The DExD/H-box family of helicases include retinoic acid–inducible gene I (RIG-I) and melanoma differentiation–associated protein 5 (MDA5), described as members of the RIG-I–like receptor (RLR) family that recognizes viral RNAs with particular structural characteristics that distinguish them from most host RNAs (Fig. 35-1). Cytoplasmic DNA receptors also have been defined, with cyclic guanosine monophosphate–adenosine monophosphate synthase (cGAS) identified as an important sensor of cytoplasmic DNA that triggers an innate immune response after interacting with the stimulator of IFN genes (STING). Whether RNA or DNA triggers these cytoplasmic sensors, the results are transcription and production of IFN-β and other pro-inflammatory cytokines that orchestrate the early phase of an antiviral immune response. The aryl hydrocarbon receptor represents an additional cytosolic receptor that can be triggered by various ligands and demonstrates crosstalk with other intracellular pathways.[15]

NOD Receptors

The nucleotide-binding oligomerization domain (NOD)–like receptor (NLR) family comprises components of an intracellular structure called the inflammasome, a signaling platform that organizes innate immune system activation in response to some stimuli.[16] The inflammasome can activate caspase 1, an enzyme important for maturation of the pro-inflammatory cytokines IL-1β and IL-18. The NLRP3-containing inflammasome has been best studied and implicated in the inflammatory response to monosodium urate crystals, the triggers of gout attacks (Chapter 252). Mutations in the *NLRP3* gene are the basis of chronic autoinflammatory syndromes that are associated with exaggerated production of IL-1 (reviewed in Chapter 240).

C-Type Lectin Receptors

Members of the C-type lectin receptor family have a carbohydrate recognition domain and a calcium-binding domain that promotes signaling after interaction with carbohydrate-expressing microbes as well as self-molecules. Dendritic cell–specific intracellular adhesion molecule-3 grabbing non-integrin (dendritic cell-SIGN) is an example of a family member that recognizes high–mannose-containing structures on foreign antigens and supports dendritic cell activation. Mannose receptors on macrophages, dendritic cells, and other cell types, such as renal mesangial cells, participate in clearance of microbes as well as antigen trapping for presentation to adaptive immune system cells. The selectin family of proteins has a lectin domain, binds to carbohydrate ligands, and mediates the first steps of leukocyte migration. L-selectin is present on virtually all leukocytes; P-selectin and E-selectin are expressed on activated endothelial cells, and P-selectin is also stored in platelets. Selectins capture floating leukocytes and initiate their attachment and rolling on activated endothelial cells.

Scavenger Receptors

Scavenger receptors comprise a diverse family of receptors with the common functional role of binding various ligands and transporting or removing nonself or altered-self targets. They can participate in clearance of microorganisms and cholesterol transport but also contribute to disease pathology. For example, among the scavenger receptors is the receptor for oxidized low-density lipoproteins, which can promote generation of lipid-laden macrophages and atherosclerosis when accumulated in excess, and receptors for relatively inert substances such as silicon, which drive an inflammatory response once taken into phagocytic cells. Scavenger receptors also participate in activation of the inflammasome, as can occur after binding serum amyloid A protein.

Immunoglobulin-like Domain-Containing Receptors

The immunoglobulin-like killer inhibitory receptor (KIR) family of receptors participates in distinguishing self-cells from cells of foreign origin or tumor cells expressing modified self-molecules. NK cells are ready to produce their toxic mediators, but they are held in check by inhibitory receptors that recognize MHC class I or MHC class I–like molecules. The observation that NK cells kill target cells lacking MHC class I molecules recognized as self led to the missing-self hypothesis. By screening cell surfaces for the expression of MHC class I molecules, the innate immune system collects information about the intactness of tissues, emphasizing the crucial role of MHC class I molecules as markers of tissue integrity. The Triggering Receptors Expressed by Myeloid cells (TREM) family of cell surface receptors has emerged as important regulators of inflammation.[17] TREM-1 synergizes with other pathogen-recognizing receptors in anti-viral responses, and TREM-2 participates in innate immunity in Alzheimer disease.[18]

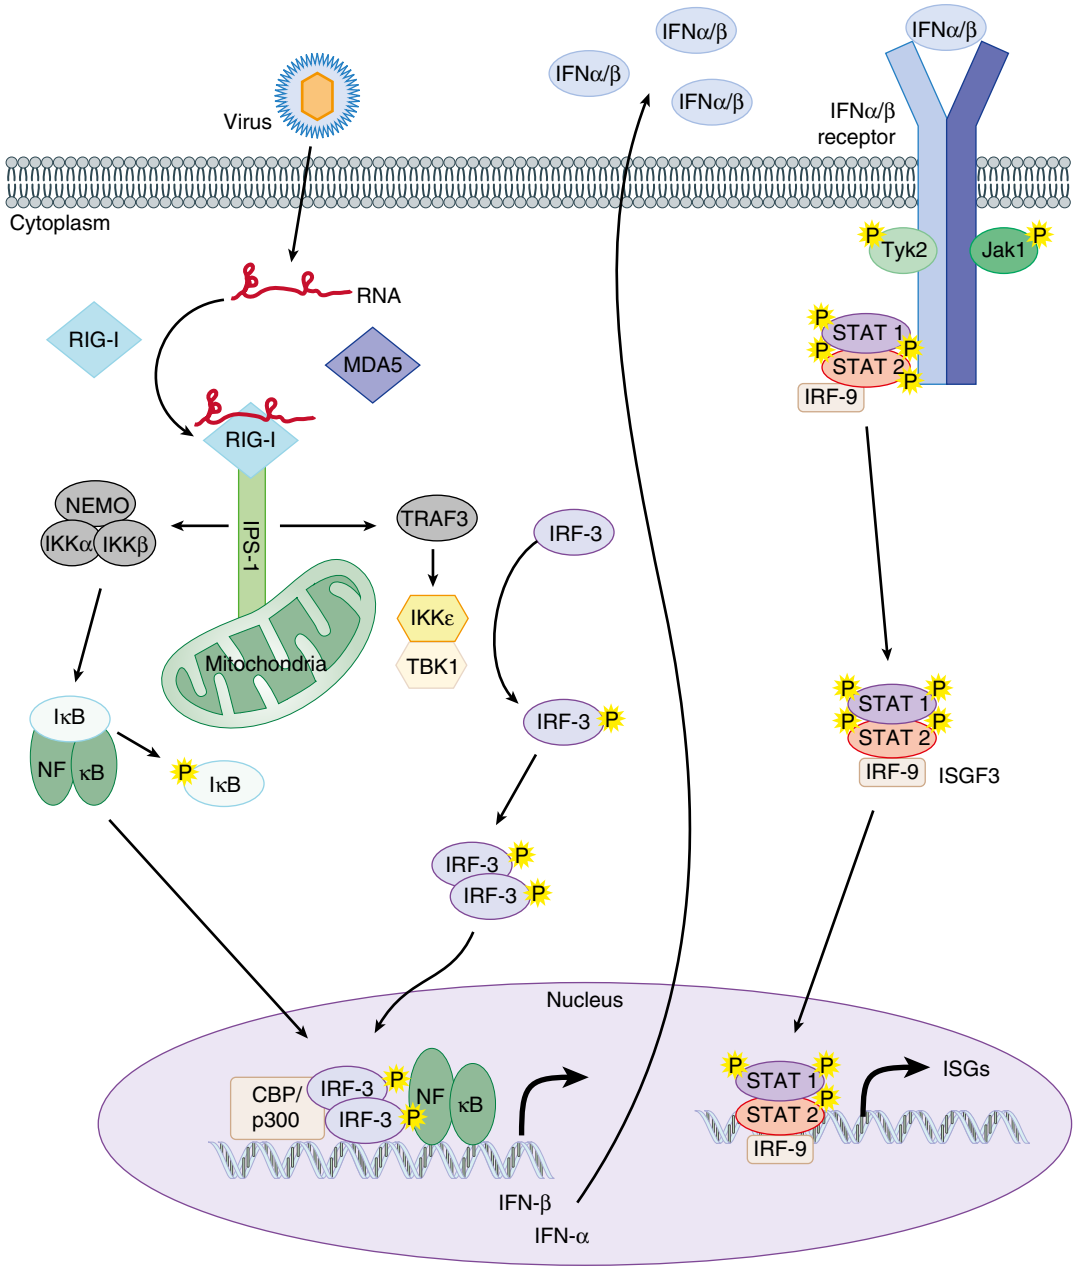

FIGURE 35-1. Induction of an antiviral type I interferon (IFN) response. Cytoplasmic sensors of RNA, including retinoic acid–inducible gene 1 (RIG-I) and melanoma differentiation-associated protein 5 (MDA5), trigger a signaling cascade that results in translocation of interferon regulatory factor 3 (IRF-3) to the nucleus and transcription of interferons. Those cytokines promote an antiviral immune response after binding to their receptor and activating the Janus kinase (JAK)–signal transducer and activator of transcription (STAT) pathway. CBP/p300 = CREB binding protein; IFN = interferon; IκB = inhibitor of κB; IKK = inhibitor of nuclear factor κB kinase subunit; IPS-1 = interferon-β promoter stimulator-1; IRF = interferon regulatory factor; ISG = interferon-stimulated gene; ISGF3 = interferon-stimulated gene factor 3; NEMO = nuclear factor-κB essential modulator; NF-κB = nuclear factor κB; P = phosphate; RIG-1 = retinoic acid-inducible gene 1; RNA = ribonucleic acid; STAT = signal transducer and activator of transcription; TBK1 = TANK-binding kinase 1; TRAF3 = TNF (tumor necrosis factor) receptor–associated factor; Tyk = tyrosine kinase. (From Wilkins C, Gale M Jr. Recognition of viruses by cytoplasmic sensors. *Curr Opin Immunol*. 2010;22:41-47.)

Fc and Complement Receptors

Most cells of the innate immune system possess FcRs that specifically interact with the constant region (Fc portion) of immunoglobulins and can bind antibodies attached to antigens. The isotype of the antibody determines which cell type is activated in a given response. Triggering of most FcRs transmits activating signals; however, inhibitory FcRs on B cells and macrophages can limit responses. Ligation of an FcγR on macrophages or neutrophils triggers phagocytosis of the antigen, activation of the respiratory burst, and induction of cytotoxicity. On NK cells, FcγRs initiate antibody-dependent cell-mediated cytotoxicity. FcRs on plasmacytoid dendritic cells are important for bringing immune complexes into endosomes containing Toll-like receptors. FcRs on mast cells, basophils, and activated eosinophils bind monomeric IgE with extremely high affinity. Cross-linking of the constitutively cell surface–bound IgE induces cell activation and the release of cytoplasmic granules. Some immunoglobulin isotypes fix complement, and complement receptors on monocytes amplify cell activation induced by antigen-antibody-complement immune complexes (Chapter 37). Complement receptor 1 (CR1) binds C3b and C4b, initial degradation products of complement activation, and when activated promotes phagocytosis of a complement-bearing immune complex. CR3 and CR4 are β_2-integrins and bind the degradation product iC3b.

Cytokine and Chemokine Receptors

Cells of the innate immune system express receptors for many cytokines, soluble low-molecular-weight glycoproteins that derive from many cellular sources. Binding of IFN-γ, produced by NK or type 1 helper T cells (T_H1 cells), by its receptor on monocytes activates a differentiation program that expands an inflammatory response. Receptors for IL-4 on monocytes induce a gene transcription program that is more supportive of a wound healing and repair program. Tumor necrosis factor-α (TNF-α) is a product of activated macrophages but also binds to those same cells through its specific receptor, expanding an inflammatory response. Innate immune cells also express receptors for IL-6, which induces acute phase reactants, and type I IFN. These

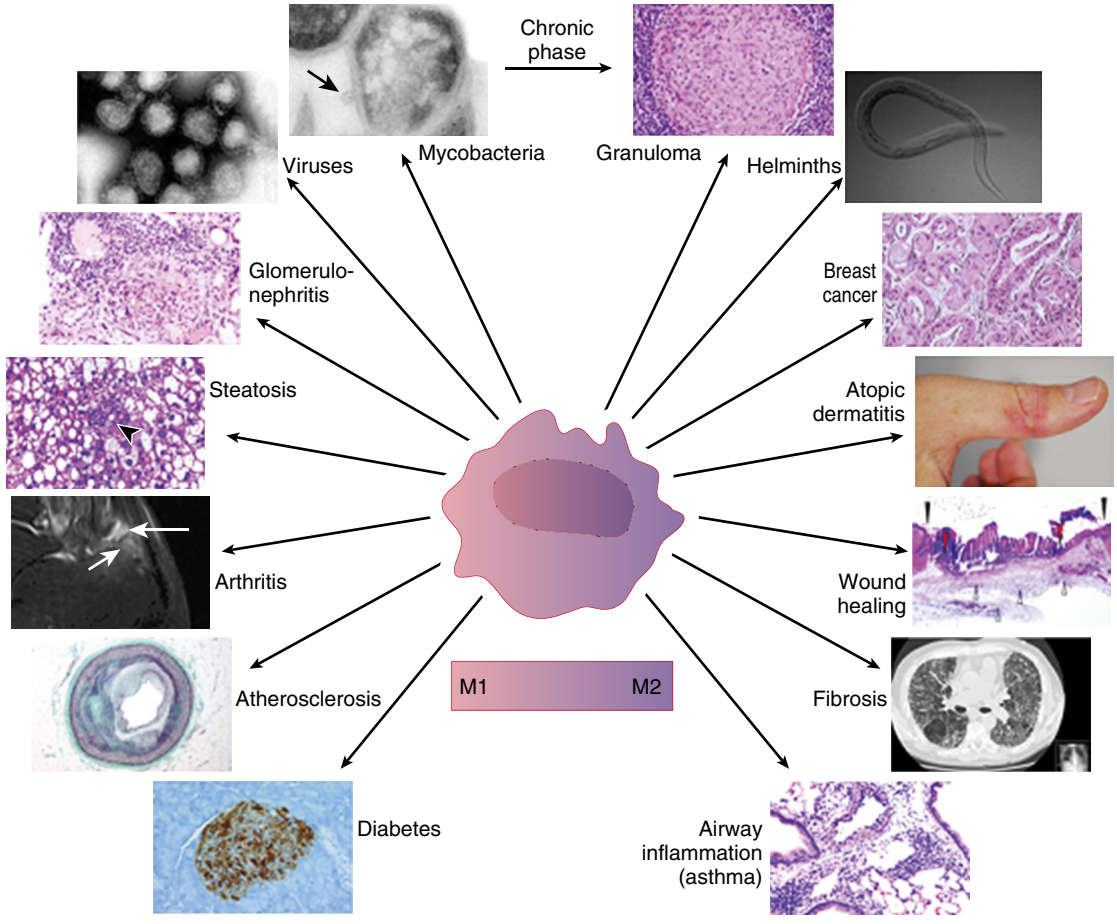

FIGURE 35-2. Schematic representation of macrophage plasticity and polarization in pathology. Dynamic changes occur over time with evolution of pathology: a switch from M1 (pro-inflammatory/classically activated) to M2 (anti-inflammatory/alternatively activated) macrophage polarization characterizes the transition from early to chronic phases of infection. Moreover, mixed phenotypes or populations with different phenotypes can coexist. (From Sica A, Mantovani A. Macrophage plasticity and polarization: in vivo veritas. *J Clin Invest*. 2012;122:787-795.)

mediators orchestrate a broad host defense program in response to virus infection (Fig. 35-2). Chemokine receptors include many family members that are differentially distributed among immune system cells and sense the gradient generated by soluble chemokines, resulting in attraction of cells to sites where they are needed to implement inflammatory or immune functions.

Signaling Pathways, Cell Differentiation, and Effector Mediators of the Innate Immune System

Each family of innate immune system receptors uses a complex network of molecules to transmit information from the cell surface or its cytoplasm to the nucleus, resulting in induction of a broad gene transcription and protein synthesis program that implements the next phase of the response. The contributions of each of the signal transduction pathways to the overall innate immune response will depend on the proteins produced and will determine whether the resulting cell products focus on ablating the damaging effects of virus infection on the host, limiting the inflammation and tissue damage that follow a bacterial or fungal infection, or healing a tissue wound through the production of scar tissue.

Receptor-Mediated Signaling Pathways

Certain common cell signaling systems are used by many cells and receptor systems. Arguably the most important is the nuclear factor κ light chain enhancer of activated B cells (NF-κB) pathway. NF-κB is a rapid-acting transcription factor because it preforms in cells of the innate immune system and does not require new protein synthesis to take action. Its activity is induced by ligation of Toll-like receptors and many cytokine receptors. Its component transcription factors translocate to the cell nucleus after degradation of an inhibitory component, inhibitor of κB (IκB), and bind to promoter regions of genes encoding mediators of inflammation and cell proliferation. Other important pathways are mediated by the IFN regulatory factor (IRF) family, including transcription factors that are activated by endosomal Toll-like receptors or by cytoplasmic nucleic acid sensors in response to ligation by DNA or RNA, usually from viral sources. IRF-3 is particularly important for promoting transcription of IFN-β, typically produced early in an antivirus innate immune response. IRF-7 is particularly supportive of IFN-α production induced by endosomal Toll-like receptors and is constitutively present in plasmacytoid dendritic cells, the most active producers of IFN-α.

The Janus kinase (JAK)–signal transducer and activator of transcription (STAT) pathway is used by many cytokine receptors and involves sequential enzymatic reactions by kinases that eventuate in translocation of STAT proteins to the nucleus, where they bind to gene promoters and induce transcription and synthesis of products important in implementing immunoregulation and inflammation.[19]

TNF receptor family members activate a complex signaling pathway that involves proteins called TNF receptor–associated death domain (TRADD) proteins and TNF receptor–associated factors (TRAFs), ultimately activating the NF-κB and the mitogen-activated protein (MAP) kinase pathways.

The TGF-β receptor is a serine/threonine receptor kinase that phosphorylates cytoplasmic proteins of the SMAD family, which act as transcription factors after receptor engagement by TGF-β. TGF-β signaling can play an important role in terminating an innate immune response and initiating a wound healing or tissue repair program.

It is apparent that common intracellular signaling strategies are used by many of the receptor systems that activate and regulate the innate immune system, with ligand-receptor engagement triggering the activation of kinases that phosphorylate downstream pathway proteins, and result in translocation of important transcription factors from cytoplasm to nucleus where new gene transcription takes place.

Soluble Products of the Innate Immune Response

Cells of the innate immune system are the principal producers of many proinflammatory and regulatory cytokines already mentioned and are also their targets. In addition to the cytokines described, cells of the innate immune system produce chemokines that attract immune system cells to sites of tissue

damage or infection, and they produce cell survival and differentiation factors that help to develop an adaptive immune response. Macrophages and dendritic cells produce IL-12 and IL-23 to support the development of effector T-cell programs, and they produce B-cell–activating factor (BAFF), a soluble member of the TNF family.[20] BAFF supports B-cell survival and can provide costimulatory signals to B cells that have received antigen-specific activation signals through their surface B-cell antigen receptors, promoting differentiation to antibody-producing plasma cells.

Components of the complement system, a group of plasma enzymes and regulatory proteins that are converted from inactive pro-enzymes to active enzymes in a controlled and systematic cascade, are crucial in linking microbial recognition to cellular effector function (Chapter 37). Mannose-binding lectin circulates in the plasma, functioning as an opsonin, and is involved in activation of the complement pathway. C-reactive protein, an acute phase protein, participates in opsonization by binding to bacterial phospholipids. Macrophages and neutrophils are important in the initiation phase of an innate immune response through their production of antimicrobial defensins, cysteine-rich cationic proteins, and cathelicidin peptides, such as LL37. Both categories of mediators can assist in killing of microbes in phagosomes. Neutrophils extrude stimulatory DNA in the form of neutrophil extracellular traps or release mitochondrial DNA, along with DNA-associated proteins like high-mobility group box 1 (HMGB1) that amplifies Toll-like receptor responses in plasmacytoid dendritic cells or macrophages.

Role of the Innate Immune System in Localization, Expansion, and Resolution of the Immune Response

Localization of Innate Immune System Cells

Most cells of the innate immune response are free agents, moving through blood or lymph in transit from one site to another. Mobility of those cells is required for effective initiation of a response to invading microbes. Cells use a multistep process of adherence and activation. Initially, leukocytes roll on activated endothelial cells, activate chemokine receptors, increase adhesiveness, and eventually migrate through the endothelial layer across a chemokine gradient. The selectin family of proteins mediates the first steps of leukocyte migration. P-selectin and E-selectin are expressed on activated endothelial cells, and P-selectin is also stored in platelets. Selectins capture floating leukocytes and initiate their attachment and rolling on activated endothelial cells. To transform attachment and rolling into firm adhesion, the concerted action of chemokines, chemokine receptors, and integrins is necessary. Integrins are heterodimers formed of many different α chains and β chains; different α/β combinations are expressed on different cell subsets. Only after activation can integrins interact with ligands on endothelial cells. Activation involves modification of the cytoplasmic domain of the β chain, which leads to a structural change of the extracellular domains. This process is termed *inside-out signaling*. The last step of homing is transendothelial migration. Here, the firmly attached leukocytes migrate through the endothelial cell monolayer and the basement membrane of the vessel wall.

Transition to an Adaptive Immune Response

Movement of innate immune system cells is also required to transition a host response from primarily one depending on cells of the innate immune system to one that engages T and B lymphocytes. Dendritic cells resident in the skin and gut serve as sentinels and a first line of defense against invading organisms. When those cells are activated following sensing of PAMPs by pattern recognition receptors and following uptake of microbial components by those cells, the dendritic cells migrate to local lymph nodes where their contents can be sampled by T cells. As noted, activated macrophages, dendritic cells, and plasmacytoid dendritic cells produce cytokines that shape the differentiation program of T cells. In addition, cell surface costimulatory molecules induced after Toll-like receptor-mediated activation, such as CD80 and CD86, provide essential accessory activation signals to T cells to ensure their effective activation. Macrophages and dendritic cells also support the development of an adaptive immune response through their production of survival and differentiation factors.

Role of Innate Immune System Cells in Resolution of an Immune Response and Wound Repair

Macrophages are particularly important in resolving an immune response and organizing the repair of damaged tissue. A classic paradigm describing pro-inflammatory/classically activated (M1) and anti-inflammatory/alternatively activated (M2) macrophages (see earlier under Monocytes and Macrophages) is likely to be overly simplistic. Yet it is clear that in the course of a chronic infection, macrophages can shift their functional profile from M1 to M2, in some cases promoted by the T-cell cytokines IL-4 and IL-13, to develop a gene expression program that includes production of TGF-β, supportive of a fibrotic response, and IL-10, a cytokine that inhibits antigen-presenting cell function. Although an M1-like profile driven by IFN-γ is highly productive in achieving initial control over a pathogenic invading microbe, and M2-derived mediators promote wound healing, it should be recognized that either macrophage phenotype, and complex in-between profiles, also can be associated with pathologic states (see Fig. 35-2). A family of polyunsaturated fatty acid (PUFA)-derived innate immune system mediators, termed specialized pro-resolving mediators, includes lipoxins, resolvins, protectins, and maresins.[21] These mediators stimulate clean up of inflammatory sites, limit further inflammation, and help to restore homeostasis following an episode of immune system activation. Current research is investigating the innate immune mechanisms that account for such diverse diseases as atherosclerosis (Chapter 65), viewed as associated with M1 macrophages, and idiopathic pulmonary fibrosis (Chapter 80), possibly involving M2-like macrophages, as well as the role of resolvins at sites of chronic inflammation such as rheumatoid synovial tissue.

CELLULAR ELEMENTS OF THE ADAPTIVE IMMUNE SYSTEM

T Cells

T precursor cells are derived from hematopoietic progenitors that migrate to the thymus, a primary lymphoid tissue, where all the subsequent stages of T-cell maturation occur (Fig. 35-3). Pre-T cells express two enzymes, RAG recombinase and terminal deoxynucleotidyl transferase, enabling them to recombine T-cell receptor genes. The β chain of the T-cell receptor is rearranged first and is expressed together with a pre-T-cell receptor α chain. Signals from the immature T-cell receptor complex induce thymocyte proliferation

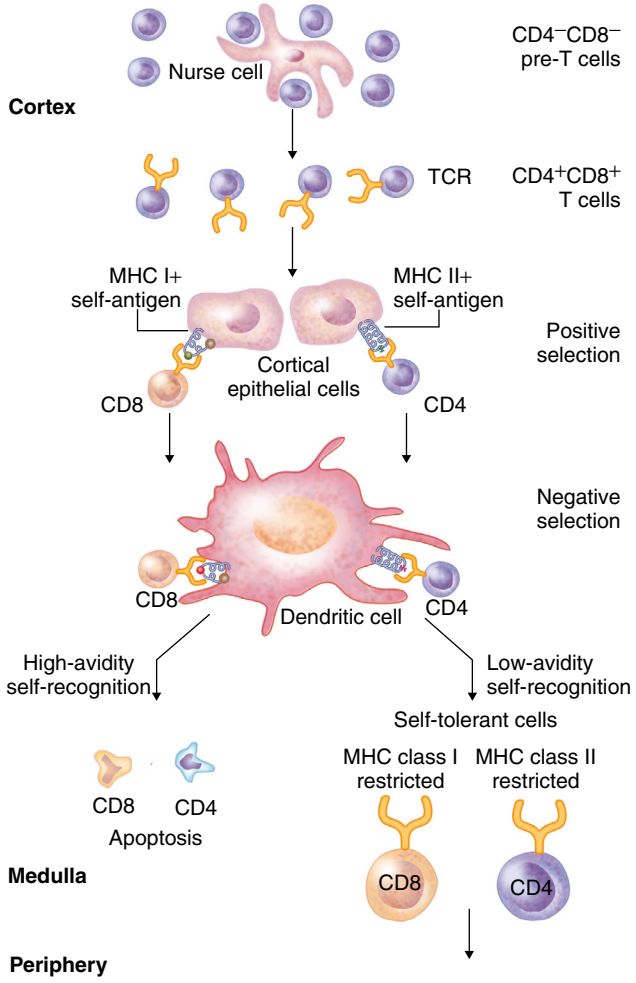

FIGURE 35-3. Maturation of T cells in the thymus. Precursors committed to the T-cell lineage arrive in the thymus and begin to rearrange their T-cell receptor (TCR) genes. Immature T cells with receptors binding to self–major histocompatibility complex (MHC) on cortical epithelial cells receive signals for survival (positive selection). At the corticomedullary junction, surviving T cells probe self-antigens presented by dendritic cells and macrophages. T cells reacting strongly to self-antigens are deleted by apoptosis (negative selection). T cells released into the periphery are tolerant toward self and recognize foreign antigens in the context of self-MHC.

and expression of both CD4 and CD8 molecules, so-called double-positive thymocytes. Subsequently, the T-cell receptor α chain is recombined, with formation of a mature T-cell receptor. From here, the thymocyte undergoes differentiation and selection steps modulated by the thymic microenvironment, thereby resulting in formation of a T cell that can migrate to secondary lymphoid tissues and is poised to recognize antigenic peptides.

Early-stage thymocytes reside in the thymic cortex, where they mostly interact with epithelial cells. They then migrate toward the medulla, encountering dendritic cells and macrophages at the corticomedullary junction. Thymic stromal cells regulate T-cell proliferation by secreting lymphopoietic growth factors, such as IL-7. Interactions of the T-cell receptor with MHC molecules expressed on epithelial cells and on dendritic cells or macrophages determine the fate of the thymocyte. Low-avidity recognition of peptide-MHC complexes on thymic cortical cells by the T-cell receptor results in positive selection, thereby rescuing cells from apoptotic cell death. Following positive selection, thymocytes migrate toward thymic medullary epithelial cells, which selectively express and present peripheral tissue antigens in order to mediate negative selection of autoreactive T cells. Thymocytes that express a receptor not fitting any MHC antigen complex die by neglect. High-affinity interaction between the T-cell receptor and peptide-MHC complex induces apoptotic death of the recognizing T cell. This process of negative selection eliminates T cells with specificity for self-antigens and is responsible for central tolerance to many autoantigens. While undergoing selection, T cells continue to differentiate. Double-positive thymocytes expressing both CD4 and CD8 engage either MHC-I or MHC-II with low-moderate affinity T-cell receptors, thereby resulting in differentiation to CD8 or CD4 single-positive T cells, respectively. These single-positive cells are now mature and ready for exit and migration to secondary lymphoid organs, including the spleen, lymph nodes, and mucosal lymphoid tissues, following chemokine cues and using adhesion molecules to enter. They exist in these tissues as quiescent naïve cells until receiving the appropriate antigenic signal for activation and development of subsequent effector function.

B Lymphocytes

Lymphoid stem cells differentiate into B-lineage cells in the bone marrow, supported by a specialized microenvironment of nonlymphoid stromal cells that supply necessary chemokines, including stromal cell–derived factor 1 (CXCL12) and cytokines (IL-7). Precursor B cells undergo sequential rearrangements of heavy chain and light chain immunoglobulin genes. On pre-B cells, the membrane μ chain is associated with a surrogate light chain to form a pre-B-cell receptor. Signals provided through this receptor induce proliferation of progeny that subsequently rearrange different light chain gene segments.

Immature B cells that express receptors directed against self-antigens are lost through negative selection and clonal deletion. Cross-linking of surface IgM by multivalent self-antigens causes immature B cells to die. Such self-reactive B cells can be rescued from death by replacing the light chain with a newly rearranged light chain that is no longer self-reactive, a process named *receptor editing*. On maturation, B cells begin additionally to express surface IgD. B cells positive for IgD and IgM are exported from the bone marrow and migrate to peripheral lymphoid tissues following a chemokine gradient (Fig. 35-4). Colocalization of T and B cells in secondary lymphoid tissues facilitates their interaction following a pathogen challenge. This response enables B cells to receive T-cell help for the former's activation and differentiation to generate memory cells and allows the antibody secretion that is required for responses to protein antigens.

PRINCIPLES OF ADAPTIVE IMMUNE SYSTEM ACTIVATION: RECOGNITION OF ANTIGEN AND GENERATION OF EFFECTOR FUNCTION

Lymphocytes and Lymphoid Tissue

The immune system uses specialized lymphoid microstructures to bring antigens to the site of lymphocyte traffic and accumulation. Secondary lymphoid organs include the spleen for blood-borne antigens, the lymph nodes for antigens encountered in peripheral tissues, and the mucosa-associated, bronchial-associated, and gut-associated lymphoid tissues, where antigens from epithelial surfaces are collected. Lymphocytes circulate through secondary lymphoid organs, constantly searching for their antigen.[22] Their homing to lymph nodes is facilitated by specialized microvessels, called high endothelial venules, which provide the proper structure for them to leave the circulation and enter the tissue. Secondary lymphoid tissues have developed several

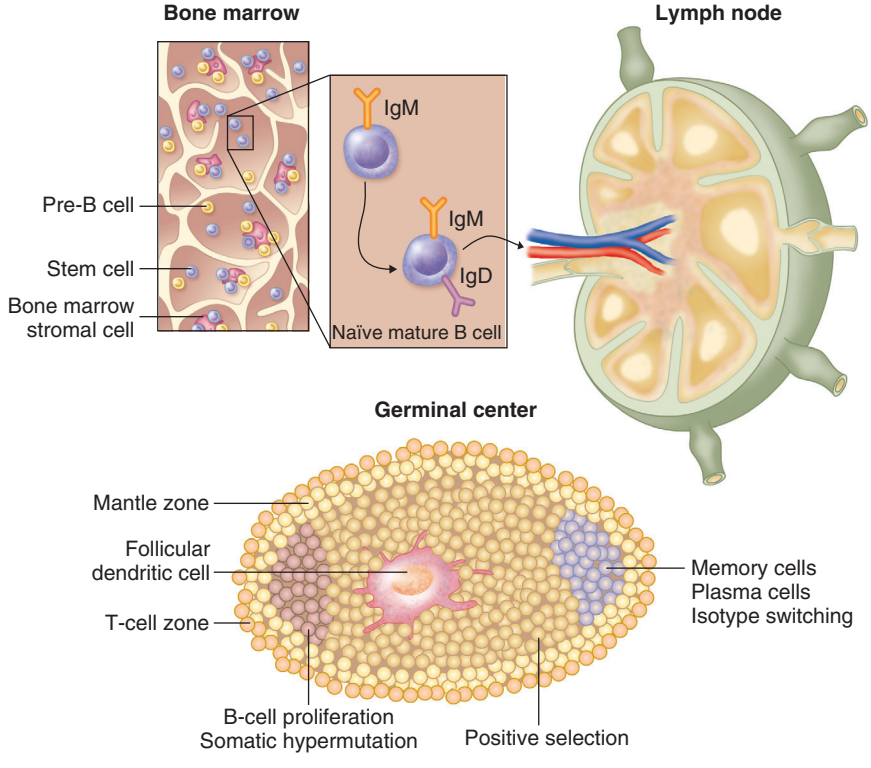

FIGURE 35-4. B-cell development and differentiation. The early stages of B-cell development occur in the bone marrow, with cells progressing through a developmental program determined by the rearrangement and expression of immunoglobulin (Ig) genes. Immature B cells with receptors for multivalent self-antigens die in the bone marrow. Surviving B cells coexpress IgD and IgM surface receptors. They are seeded into peripheral lymphoid organs, where they receive signals to survive. Antigen-binding B cells and antigen-presenting B cells that receive help from antigen-specific T cells are activated through membrane-bound and secreted molecules. Activated B cells migrate into the follicles, forming germinal centers, and undergo somatic hypermutation of immunoglobulin genes. Cells with high affinity for antigens presented on the surface of follicular dendritic cells are selected to differentiate into long-lived antibody-secreting plasma cells that migrate to the bone marrow. Cells differentiating into long-lived memory B cells have a range of antigen affinities, enabling more diverse responses upon reinfection by pathogens.

strategies to sequester the relevant antigen. Antigens in peripheral tissue are encountered first by dendritic cells that, after activation, are mobilized to transport antigens into the local lymph nodes by the draining lymph. These antigen-bearing dendritic cells enter the lymph nodes through the afferent lymphatic vessel and settle in the T-cell–rich zones to present processed antigens to T cells. The net result of this process is an accumulation and concentration of the antigen in an environment that can be readily screened by infrequent antigen-specific T cells.

B cells are segregated from T cells in the lymph nodes and are localized in follicles. Naïve B cells may engage antigen as they circulate through secondary lymphoid tissues, for example as presented to them by migratory dendritic cells or macrophages in the subcapsular region of lymph nodes. If, on antigen engagement, B cells find their cooperating (cognate) T cells at the borders of the T-cell–rich areas and the follicle, they both receive cues to enter germinal centers and send similar signals back to their cognate follicular helper T cells. Germinal centers contain a network of follicular dendritic cells that capture particulate antigen or immune complexes on the cell surface. This unprocessed antigen is taken up by antigen-specific B cells, processed and presented, and recognized by antigen-specific T_{FH} cells. Germinal centers are essential for generating long-lived antibody-secreting plasma cells and memory B cells.

Antigen Processing and Presentation

T cells bearing α/β T-cell receptors recognize peptide fragments that are displayed in the context of MHC class I and class II molecules through a process termed antigen presentation. The two classes of MHC molecules are used as restriction elements by two different subsets of T cells. $CD4^+$ T cells recognize antigenic peptides embedded into MHC class II molecules, whereas $CD8^+$ T cells bind peptides complexed with MHC class I molecules. Generally, MHC class II molecules are expressed only on specialized, so-called professional, antigen-presenting cells, such as dendritic cells, monocytes, macrophages, and B cells, whereas class I proteins are displayed by virtually all nucleated cells, facilitating recognition by $CD8^+$ T cells of peptides from viruses that often have a broad range of target tissues. Peptides bound to MHC class II molecules typically derive from extracellular antigens that are captured and internalized into endosomes to be digested by proteinases, notably cathepsin. Occasionally, however, intracellular proteins or membrane proteins are also funneled into this pathway. MHC class II molecules are assembled in the endoplasmic reticulum in association with a protein called the invariant chain (Fig. 35-5). The molecules are transported to the endosome, where the invariant chain is removed from the peptide-binding cleft, making the cleft accessible to peptides derived from extracellular proteins. MHC class II molecules, stabilized by peptides of 10 to 30 amino acids in length, are displayed on the cell surface, where they are recognized by $CD4^+$ T cells.

MHC class I–associated peptides are generated in the cytosol by the proteasome, a large cytoplasmic multiprotein enzyme complex (see Fig. 35-5), thereby allowing killer $CD8^+$ T cells to recognize microbial peptides produced within infected cells. Specialized transporter proteins, called transporter in antigen processing (TAP), facilitate translocation of peptides from the cytosolic proteasome to the endoplasmic reticulum. There, the peptides bind to newly formed MHC class I molecules and are transported to the cell surface, where they are recognized by antigen-specific $CD8^+$ T cells. MHC class I–associated peptides may also originate in the extracellular environment and be presented to T cells through the appropriately named cross-presentation pathway. This pathway enables $CD8^+$ T cells to recognize foreign peptides (e.g., from viruses) that are derived from infected and dying cells that are ingested by myeloid cells and then presented by MHC class I molecules.

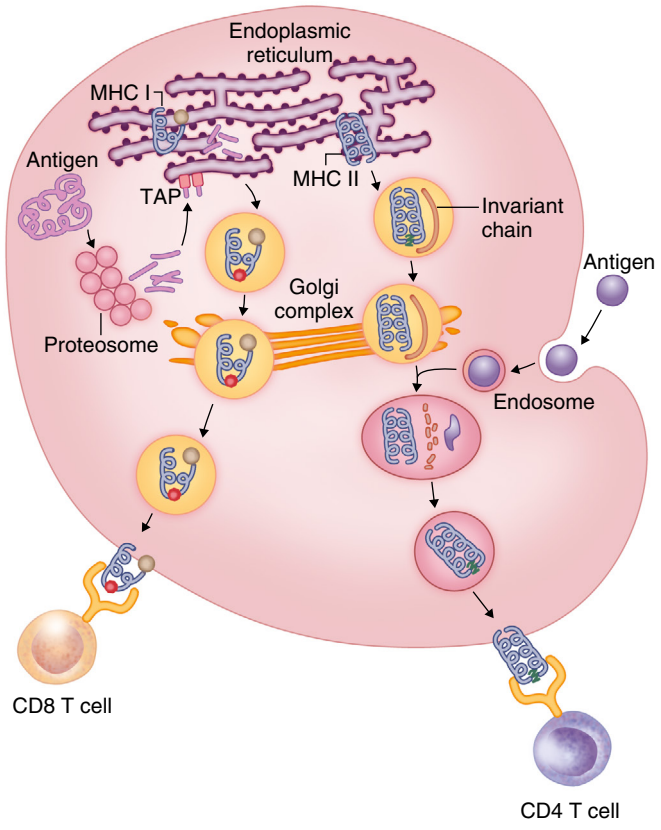

FIGURE 35-5. Pathways of antigen processing and delivery to major histocompatibility complex (MHC) molecules. Cytosolic proteins are broken down by the proteosome to generate peptide fragments, which are transported into the endoplasmic reticulum by specialized peptide transporters (TAP). After peptides are bound to MHC class I molecules, MHC-peptide complexes are released from the endoplasmic reticulum and travel to the cell surface, where they are ligands for $CD8^+$ T-cell receptors (TCRs). Extracellular foreign antigens are taken into intracellular vesicles, called *endosomes*, and proteases are activated that digest antigens into peptide fragments. After fusing with vesicles that contain MHC class II molecules, antigenic peptides are placed in the antigen-binding groove. Loaded MHC class II–peptide complexes are transported to the cell surface, where they are recognized by the TCRs of $CD4^+$ T cells.

Structure of Antigen-Specific Receptors

T-Cell Receptors

T-cell receptors are dimers of α chains and β chains or of γ chains and δ chains, each of which contains three complementarity-determining binding sites in the N-terminal domain. These complementarity-determining sites define the specificity of the T-cell receptor. Most α/β T-cell receptors recognize peptide fragments in the context of MHC molecules, although certain ones bind glycolipid antigens, for example, from mycobacteria, displayed by molecules with structural similarity to MHC. γ/δ T-cell receptors are more variable and can recognize peptides or certain glycolipid antigens in the context of MHC-like molecules, or even unprocessed antigens.

Antibodies

Antibodies consist of two identical heavy chains and two identical light chains, which are covalently linked by disulfide bonds. The amino (N)-terminal domain of each chain is variable and represents the recognition structure that interacts with the antigen. Each antibody has two binding arms of identical specificity. The carboxy (C)-terminal ends of the heavy and light chains form the constant region, which defines the subclass of the antibody (κ or λ for light chains; IgM, IgA, IgD, IgE, or IgG for heavy chains). Additional subclasses can be distinguished for IgG and IgA. The constant region of antibodies includes the Fc region. Fc regions can polymerize (IgA) or pentamerize (IgM), both in the presence of a J (joining) chain. Fc regions are also the ligand for Fc receptors (FcRs) on cells of the innate immune system.

Specificities of T-Cell Receptors and Antibodies

The repertoires, or total number of specificities, of T-cell receptors and antibodies are extremely diverse and have been estimated in the human to account for up to 10^{18} or higher and 10^{11} combinations, respectively. This enormous diversity reflects the anticipatory nature of adaptive immune receptors and must be acquired; it cannot be genetically encoded in contrast to that of innate receptors. T-cell receptor β chains and δ chains are assembled by the recombination of variable, diversity, joining, and constant region segments of T-cell receptor genes. Immunoglobulin heavy chains are formed from four gene segments—the variable, diversity, joining, and constant region gene segments. Also, immunoglobulin light chains and T-cell receptor α chains and γ chains lack the diversity segment and are composed of three gene segments. During T-cell receptor or antibody rearrangement, gene segments are cut out by nucleases and recombined at the DNA level to form linear coding units for each receptor gene. An enormous diversity of receptors is generated as each receptor or antibody uses a different combination of gene segments; the recombination and repair process is imprecise, introducing nucleotide variations at the variable-diversity, diversity-joining, and variable-joining junctions; and random nucleotides can be inserted at the junctional region by an enzyme, terminal deoxyribonucleotidyl transferase.

Once generated, T-cell receptor sequences remain unchanged. This rule does not apply to immunoglobulins, which undergo modification, including replacement of an entire variable region, or receptor editing, to modify those receptors that inadvertently bind self-antigens; class switching, in which the variable-diversity-joining unit combines with different constant region genes; or somatic hypermutation, in which the antigen-contact areas of the antibody undergo mutations to improve the affinity. The latter two events occur in secondary lymphoid tissues, such as the spleen, lymph nodes, and mucosal lymphoid tissue, where immune responses to antigens are initiated.

T-Cell Stimulation and Accessory Molecules

MHC-peptide recognition by the T-cell receptor, the first signal for T-cell activation, leads to receptor clustering and phosphorylation of the intracellular portion of the CD3 protein complex, the signaling component of the receptor, by receptor-associated tyrosine kinases. These events transmit signals to the nucleus and initiate activation of the T cell. The coreceptors CD4 and CD8, through their interaction with MHC class II and class I molecules, respectively, support CD3-mediated signals. This first activation signal delivered by the T-cell receptor and coreceptors needs to be complemented by the interaction of accessory molecules on the T cell and their ligands on the antigen-presenting cell. A spectrum of accessory molecules has been identified, of which the best known is CD28, which are engaged by CD80 and CD86 on antigen-presenting cells. Engagement of CD28 provides to the T cells a second, or costimulatory, signal that ensures T-cell survival and expansion. CD28-mediated signals are mandatory for the expression of many activation markers on the responding T cells and, in particular, for the secretion of IL-2. In the absence of such a second signal, T cells are rendered nonresponsive and anergic or undergo apoptosis. Additionally, adhesion molecules (integrins) stabilize the interactions between T cells and antigen-presenting cells. Signals from the T-cell receptor result in the activation of many genes and entry of the T cell into the cell cycle.

Three major variables determine the outcome of T-cell receptor stimulation: the duration and affinity of the T-cell receptor-antigen interaction, the maturation stage of the responding T cell, and the nature of the antigen-presenting cell. Antigen-presenting cells are gatekeepers in the initiation of T-cell responses. They can upregulate the expression of accessory molecules that provide costimulatory signals. MHC-peptide complexes are particularly dense on dendritic cells, enabling them to activate naïve T cells. In contrast, memory and effector cells have a lower threshold for activation and can react to antigens presented on peripheral tissue cells.

Another set of accessory molecules can limit the activation of T cells and have been identified as therapeutic targets, with inhibitors promoting activation and expansion of T cells with potential to inhibit or eliminate tumor cells.[23] CTLA-4 and PD-1 are expressed on T cells after cell activation and limit their expansion when ligated by CD80 or CD86 or PD-L1, respectively, but the so-called immune checkpoint inhibitors block those accessory molecules, with the goal of reversing peripheral tolerance to tumor antigens.

B-Cell Stimulation and Accessory Molecules

Mature, but naïve, B cells in secondary lymphoid organs are activated by soluble and cell-bound antigens to develop into antibody-secreting effector cells. B cells respond to a large variety of antigens, including proteins, polysaccharides, and lipids. Binding of antigen to cell surface IgM molecules induces B-cell receptor clustering, the initial step in B-cell activation. In addition to the antigen-binding immunoglobulin, the B-cell receptor comprises two proteins, Ig-α and Ig-β. The Ig-α/Ig-β heterodimer functions to transduce a signal and initiates the intracellular signaling cascade, analogous to the CD3 molecule of the T-cell receptor. Thus, the composition of the B-cell receptor, with ligand-binding and signal-transducing units, and the signaling events that lead to gene induction, are similar to those of the T-cell receptor. Both receptors are enhanced by coreceptors. The B-cell receptor-coreceptor complex is composed of CD81, CD19, and CD21, analogous to the T-cell receptor coreceptors CD4 and CD8. CD21 binds to complement fragments on opsonized antigens that are bound by the B-cell receptor, thereby resulting in phosphorylation of the intracellular tail of CD19 by tyrosine kinases and augmentation of the B-cell receptor–mediated signal.

Like naïve T cells, naïve B cells require accessory signals in addition to triggering of their antigen-binding receptor. They receive second signals either from follicular helper T cells or from thymus-independent antigens such as bacterial polysaccharides that can induce antibody production in the absence of helper T cells.[24] In contrast, in the case of protein antigens, which are thymus- or T-dependent, the initial B-cell receptor stimulation prepares the cell for subsequent interaction with follicular helper T cells. These activated B cells start to enter the cell cycle; upregulate cell surface molecules, such as CD80 and CD86, which provide costimulatory signals to T cells; and upregulate certain cytokine receptors. As such, these B cells are prepared to activate helper T cells and to respond to cytokines secreted by those T cells, but they cannot differentiate into antibody-producing cells in the absence of T-cell help. Survival and differentiation factors produced by myeloid cells, such as B-cell–activating factor, also stimulate B cells and help to maintain the B-cell pool.

Signaling Pathways, Cell Differentiation, and Effector Mediators of the Adaptive Immune System

T-Cell Differentiation

T-cell activation induces T-cell proliferation, with the goal of clonally selecting and expanding antigen-specific T cells. Antigen-specific $CD8^+$ T cells expand several thousand–fold; $CD4^+$ T cells expand somewhat less. During the phase of rapid growth, T cells differentiate from naïve T cells that are essentially devoid of effector functions into effector T cells that are needed for clearance of infectious organisms, or pathogens. The transition into effector cells is associated with a fundamental shift in functional profiles. First, effector T cells do not require costimulation to function and can scan tissues that lack professional antigen-presenting cells. Second, they switch the expression of chemokine receptors and adhesion molecules to gain access to peripheral tissues. Finally, they gain effector functions.

The principal effector function of $CD8^+$ T cells is to lyse infected, antigen-bearing target cells. On activation, $CD8^+$ T cells acquire cytotoxic functions and, using a variety of receptors and adhesion molecules, can emigrate from secondary lymphoid organs to peripheral tissue sites seeking cells infected by viruses or intracellular bacteria displaying pathogen-derived peptides on MHC class I molecules. On recognizing the appropriate MHC class I–peptide complex, $CD8^+$ T cells induce apoptosis of target cells using specialized lytic granules. A pore-forming protein, perforin, is released from the lytic granules and inserted into the target cell membrane. Proteases (granzymes) are injected into the target cells to initiate the apoptotic process by activating enzyme cascades. $CD4^+$ T cells can also induce apoptosis but by a different mechanism. On activation, they express cell surface molecules such as Fas ligand (CD178) and TRAIL, which initiate the apoptotic cascade selectively in cells expressing the respective ligands Fas (CD95) or the death receptors DR4 and DR5.

Compared with $CD8^+$ T cells, the spectrum of options for $CD4^+$ T cells is larger. They are generally characterized as helper T, or T_H, cells because they produce cytokines and express cell surface molecules that promote the effector function of other lymphocytes and phagocytes. On activation, different subsets of $CD4^+$ effector T cells can be distinguished based on the preferential production of certain cytokines (see E-Table 35-1). T_H1 T cells predominantly produce IFN-γ and tumor necrosis factor-α (TNF-α) and are involved in cell-mediated immunity, such as delayed-type hypersensitivity reactions. These cytokines, among other actions, promote macrophage activation that is critical for protective responses against intracellular pathogens such as mycobacteria and listeria. T_H2 T cells preferentially produce IL-4, IL-5, and IL-13, cytokines that promote eosinophil maintenance, expansion, and tissue accumulation, as well as macrophage function; these are all important for host protection following infection with helminths, such as schistosomes and other worms. T_H17 T cells produce IL-17, critical for neutrophil expansion and function, with killing of extracellular bacteria, such as streptococci, and pathogenic fungi. These cells may also produce IL-22 that promotes host-protective function at barrier surfaces, such as the skin and gut. Follicular helper T (T_{FH}) cells home to lymphoid follicles, where B cells congregate, where they express CD40 ligand (CD154) and other surface proteins along with cytokines, including IL-21, IL-4, and IFN-γ, that are critical for B-cell maturation to plasma cells and memory B cells. The decision as to which differentiation pathway to take is made during the early stages of naïve T-cell activation by antigen-presenting cells in secondary lymphoid organs. Pathway differentiation depends on several factors, including (1) the cytokines produced by the activating antigen-presenting cell and other innate cells in the microenvironment, (2) the nature of costimulatory signals, and (3) the avidity of the T-cell receptor-MHC antigen interaction. $CD4^+$ T-cell subset, or lineage, development is generally correlated with the expression of specific transcription factors (T-bet for T_H1, GATA3 for T_H2, RORγt for

E-TABLE 35-1 CYTOKINES AND CYTOKINE FUNCTION

CYTOKINES	MAJOR PRODUCER CELLS	PRINCIPAL ACTION
HEMATOPOIETIN FAMILY		
IL-2	T cells	Proliferation of T cells, B cells, and NK cells
IL-3	T cells	Early hematopoiesis
IL-4	T cells, mast cells	B-cell activation, IgE switch, inhibition of T_H1 cells
IL-5	T cells, mast cells	Eosinophil growth and differentiation
IL-6	Macrophages, endothelial cells	T-cell and B-cell growth and differentiation, induction of acute phase proteins
IL-7	Bone marrow, thymic epithelium	Growth of pre-B cells and pre-T cells
IL-9	T cells	Stimulation of mast cells and T_H2 cells
IL-11	Stromal fibroblasts	Hematopoiesis
IL-13	T cells	B-cell growth and differentiation, inhibition of T_H1 cells and macrophages
G-CSF	Fibroblasts and monocytes	Neutrophil development and differentiation
IL-15	Non-T cells	Growth of T cells and NK cells
GM-CSF	Macrophages, T cells	Growth and differentiation of myelomonocytic lineage cells
INTERFERON FAMILY		
IFN-α	Plasmacytoid dendritic cells, other leukocytes	Antiviral, induction of coordinated interferon-stimulated gene transcriptional response
IFN-β	Fibroblasts	Antiviral, induction of coordinated interferon-stimulated gene transcriptional response
IFN-γ	T cells, NK cells	Macrophage activation, increases expression of MHC molecules, Ig class switching, inhibition of T_H2 cells
TUMOR NECROSIS FACTOR FAMILY		
TNF-α	Macrophages, NK cells, T cells	Induction of pro-inflammatory cytokines, endothelial cell activation, apoptosis
TNF-β (LT-α)	T cells, B cells	Cell death, endothelial activation, lymphoid organ development
LT-β	T cells, B cells	Cell death, lymphoid organ development
OTHERS		
TGF-β	Monocytes, T cells	Anti-inflammatory, inhibits cell growth, induces IgA secretion
IL-1α, IL-1β	Macrophages, endothelial cells	Acute phase response, fever, macrophage activation, costimulation
IL-10	T cells, macrophages	Suppression of macrophage functions
IL-12	Macrophages, dendritic cells	NK cell activation, T_H1 cell differentiation
IL-16	T cells, mast cells, eosinophils	Chemoattractant for CD4 T cells, monocytes, and eosinophils
IL-17	CD4 T cells	Cytokine production by epithelia, endothelial cells, and fibroblasts
IL-18	Macrophages	IFN-γ production by T cells and NK cells
IL-23	Macrophages, dendritic cells	T_H17 cell differentiation

CD = cluster of differentiation; G-CSF = granulocyte colony-stimulating factor; GM-CSF = granulocyte-macrophage colony-stimulating factor; IFN = interferon; Ig = immunoglobulin; IL = interleukin; LT = lymphotoxin; MHC = major histocompatibility complex; NK = natural killer; TGF = transforming growth factor; T_H = helper T lymphocyte; TNF = tumor necrosis factor.

T_H17, and Bcl6 for T_{FH} cells). However, lineage commitment among differentiated $CD4^+$ T cells is not absolute, and transition between different effector types is possible.

Regulatory T Cells

Depending on their cytokine profile, $CD4^+$ T cells have the ability to cross-regulate each other, influence T-cell differentiation, and suppress T-cell effector activity. T cells with regulatory activity generated during the normal immune response are IL-10– and transforming growth factor-β (TGF-β)–producing cells. In addition, specialized subsets of regulatory T (Treg) cells are characterized by expression of the transcription factor forkhead box P3 (Foxp3).[25] Naturally occurring $Foxp3^+$ Treg cells are generated during T-cell development in the thymus and recognize self-antigens. $Foxp3^+$ Treg cells can also arise from conventional $CD4^+$ T cells in the periphery. Treg cells are important in peripheral tolerance, controlling the expansion of autoreactive T cells. They also play a role in immune responses to pathogens by virtue of their ability to suppress T-cell effector function and consequently downmodulate the inflammatory response incited by the former, a natural consequence of pathogen elimination. Treg cells may also specialize according to their tissue environment, for example, selectively to regulate inflammation promoted by T_H1, T_H2, and T_H17 cells, respectively, and to regulate T_{FH} cells that drive production of autoantibodies by B cells in autoimmune diseases. A principal difference between natural and induced Treg cells is that the latter largely survey mucosal and other environmentally exposed surfaces.

In addition to secretion of IL-10 and TGF-β, which can dampen inflammatory responses, and functioning as a sink for pro-inflammatory cytokines such as IL-2, Tregs may also express the T-cell molecule cytotoxic T-lymphocyte antigen (CTLA)-4 (CD152) that, like CD28, engages CD80 and CD86 on antigen-presenting cells. In contrast to CD28, which receives a positive signal from CD80 and CD86, engagement of these molecules on antigen-presenting cells by CTLA-4 on Tregs suppresses the ability of antigen-presenting cells to activate naïve T cells.

T-Cell Homeostasis

Effective immunity depends on the ability of the immune system to generate large numbers of antigen-specific T cells rapidly, yet the space in the T-cell compartment is limited. To avoid competition for space and resources and to prevent perturbation of T-cell diversity by lifelong exposure to antigens, the adaptive immune system employs several counterbalancing mechanisms. In the later stages of the activation process, a strong negative signal derives from interaction of CTLA-4 with CD80/CD86 on antigen-presenting cells. In addition, T cells undergo activation-induced cell death. Activated $CD4^+$ T cells begin to secrete Fas ligand and acquire sensitivity to Fas-mediated death, inducing apoptotic suicide and fratricide in neighboring T cells. These mechanisms impose constraints in the early stages of the T-cell antigen response. Other mechanisms control the rapid decline of expanded antigen-specific T cells when elimination of the antigen has been achieved. Removal of the driving antigen causes a deprivation of cytokines and costimulatory molecules, and growth factor–deprived T cells die from apoptosis. It has been estimated that only 5% of the antigen-expanded population survives after antigen clearance, becoming memory cells that are poised to respond if the host is again challenged by the same offending pathogen.

B-Cell Differentiation

Differentiation of B cells activated by protein antigens depends on interaction with helper T cells. B cells use their antigen receptor not only to recognize antigens but also to internalize them. After processing endocytosed antigens, MHC class II–peptide complexes appear on the cell surface, where antigen-specific $CD4^+$ T cells detect them. Also, B cells express costimulatory molecules and provide optimal conditions for T-cell activation. On activation, $CD4^+$ T cells express CD154, also known as CD40 ligand, on their surface and are able to stimulate the CD40 molecule on their B-cell partner. CD40-CD154 interaction is essential for subsequent B-cell proliferation and differentiation. Cytokines secreted by the helper T cells act in concert with CD154 to amplify B-cell differentiation and to determine the antibody type by controlling isotype switching. Cytokines drive isotype switching by stimulating the transcriptional activation switch regions upstream of heavy chain constant region genes and ultimately facilitating excision of the IgM heavy chain gene and recombination of the VDJ segments with one of the downstream constant regions, IgG, IgA, or IgE. A population of B cells that is prominent in aging, in autoimmune disease and after virus infection or vaccination, called age-associated B cells (ABCs), appears to require signals through endosomal TLR-7, along with B-cell receptor and cytokine signals, for differentiation to autoantibody-secreting cells.[26]

T-cell–dependent B-cell differentiation and maturation take place in germinal centers, specialized areas in secondary lymphoid tissues where B cells rapidly proliferate and mutate the variable, or antigen-binding portion, of their immunoglobulin surface receptors. Those B cells bearing receptors with mutations that confer the highest affinity for antigen are selected for survival with the help of specific signals delivered by follicular helper T cells, whereas those with mutations conferring lesser affinity die by apoptosis. This process enables affinity maturation of B cells that most efficiently bind antigen and thereby facilitate antigen removal and pathogen clearance.

Generating Memory and Tolerance

Memory

An important consequence of adaptive immunity is the generation of immunologic memory, the basis for long-lived protection after a primary infection. Memory induction by vaccination is one of the landmark successes in medicine. Immunologic memory is defined as the ability to respond more rapidly and effectively to pathogens that have been encountered previously. As a direct result of clonal expansion and selection in antigen-driven responses, the frequencies of antigen-specific memory B cells and memory T cells are increased 10-fold to 1000-fold compared with the naïve repertoires. In addition to increased frequencies, memory T cells and B cells are functionally different from their naïve counterparts. Memory cells are long-lived and survive in the presence of certain cytokines without the need for continuous antigenic stimulation, guaranteeing immunologic memory for the life expectancy of the individual cell. Memory B cells produce predominantly IgG and IgA antibodies with evidence of somatic hypermutation and high affinity for the antigen. High-affinity IgE antibodies are also produced upon challenge with certain pathogens, such as helminths, and upon allergen exposure. Cell surface expression of high-affinity antibodies allows more efficient antigen uptake, thereby enhancing the crucial interaction with T cells. On antigen encounter, memory B cells change to antibody-secreting plasma cells, or re-enter the germinal center, where the high affinity of their immunoglobulin receptor gives them a competitive advantage over naïve B cells in antigen binding, leading to affinity maturation of somatically mutated antibody molecules.

Because the T-cell receptor does not undergo isotype switching or affinity maturation, memory T cells are more difficult to distinguish from naïve or effector T cells. Memory T cells lack activation markers and need antigen stimulation to resume effector functions. In contrast to naïve T cells, memory T cells have a lower activation threshold and are less dependent on costimulatory signals. In essence, their requirements for antigen stimulation are fewer, and their clonal size is larger, permitting fast, efficient responses to secondary antigen encounters.

Tolerance

Unresponsiveness to self is a fundamental property of the immune system and is required to maintain tissue integrity of the host. Because of the extraordinary complexity and variability of the repertoires of T- and B-cell antigen receptors, mechanisms of self/nonself discrimination are particularly applicable to the adaptive immune system. For T and B cells, antigen-specific receptors are generated randomly, and the entire spectrum of antigens can be recognized. Several different mechanisms are used, collectively called *tolerance*.[27] Tolerance in the adaptive immune system is antigen specific, and failure of self-tolerance results in immune responses against self-antigens. In central tolerance, self-reactive lymphocytes are deleted during development. In the bone marrow, B cells that express receptors directed against self-antigens are eliminated through clonal deletion. The process of negative selection is particularly important for T cells, and mutations in a gene called *AIRE* are associated with failure to delete self-reactive cells effectively in the thymus.[28] Even in the healthy setting, not all self-reactive T cells are centrally purged from the repertoire, and all T cells have some degree of self-reactivity, which is necessary for positive selection in the thymus and peripheral survival. Mechanisms of peripheral T-cell tolerance include (1) anergy, (2) peripheral deletion, (3) clonal ignorance, and (4) suppression of immune responses by regulatory T cells. T-cell anergy is transient and is actively maintained. MHC-peptide presentation to T cells by immature or inactivated, resting antigen-presenting cells or on cells other than peripheral antigen-presenting cells results in anergy because of the lack of expression of costimulatory molecules. Peripheral deletion is induced as a consequence of hyperstimulation.

Hyperstimulation of T cells (e.g., by high doses of antigen and high concentrations of IL-2) preferentially activates pro-apoptotic pathways and causes elimination of the responding T-cell specificity. Clonal ignorance is defined as the presence of self-reactive lymphocytes that fail to recognize or respond to peripheral antigens. These cells remain responsive to antigenic challenge if given in the right setting. An example of clonal ignorance is nonresponsiveness to sequestered antigens that are not accessible to the immune system. Treg cells play a pivotal role in maintaining peripheral tolerance. Harnessing the frequencies and function of Foxp3 $CD4^+$ T cells may offer a promising approach to restoring peripheral tolerance in treating autoimmune diseases or facilitating transplantation tolerance.

A critically important mechanism of peripheral B tolerance is maintained through the absence of T-cell help. B lymphocytes that recognize self-antigens in the periphery in the absence of T-cell help are rendered anergic or are unable to enter lymphoid follicles, where they could receive T-cell help, effectively excluding them from immune responses.

CONTRIBUTION OF THE INNATE AND ADAPTIVE IMMUNE RESPONSES TO PATHOGENESIS OF DISEASE

Immunodeficiency and Autoimmunity

Characterization of genetic polymorphisms and mutations in immune system genes that are associated either with apparent vulnerability to infection or inappropriate self-reactivity and autoimmunity has provided important insights into immune mechanisms that are essential for host defense and maintenance of immune tolerance. Mutations in components of innate and adaptive immune system pathways that recognize, respond to, or regulate the response to viruses or bacteria characterize immunodeficiencies that can be life-threatening (see Chapter 231).[29] In some cases, those vulnerabilities are revealed only in the setting of an infection with an agent not previously encountered. For example, recent reports describe previously healthy men who developed severe disease in the setting of severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2) infection and were found to have mutations in the *TLR7* gene, thereby impairing the type I IFN response.[30]

Autoimmune and inflammatory diseases occur in about 5% of the general population. The mechanisms that account for the generation of autoreactive T cells, responses directed to modified self-antigens, and the well-established associations of certain MHC alleles with autoimmune diseases are areas of active investigation.[31] Although many autoimmune diseases may result from failure of tolerance mechanisms or dysfunction of the regulatory pathways that control adaptive immune responses, excessive activation of an innate immune response can set the stage for a self-reactive T- or B-cell response. Polymorphisms in genes encoding components of innate immune signaling pathways can amplify an immune response, thereby resulting in increased and sustained production of type I IFN, IL-1, or TNF-α. Endogenous ligands with potential to activate Toll-like receptors can act as effective immune stimuli in the setting of a pro-inflammatory environment associated with oxidative or apoptotic cell damage. Alterations in degradation of endogenous RNA and DNA based on single-gene mutations can result in activation of cytosolic nucleic acid sensors, sustained type I IFN production, skin lesions, and central nervous system involvement in diseases termed type I interferonopathies.[32] The inflammasome and its component proteins, including the NOD-like receptors, are recognized as mediators of inflammatory responses induced in some autoinflammatory syndromes (Chapter 240).

Many models of autoimmunity rely on the hypothesis that peripheral anergy is broken. Microbial infection or bacterial components in the gut microbiome (Chapter 257) may trigger an immune response that primes the immune system for an exaggerated and self-directed response to a subsequent trigger through epigenetic modifications.[33] Autoreactive B cells that recognize self-antigen complexed with foreign antigen may result in activation of T cells specific for the foreign antigen that then provide help to B cells specific for the self-antigen. Tolerance mechanisms of anergy or clonal ignorance can fail if a foreign antigen is sufficiently different from a self-antigen to initiate an immune response but sufficiently similar for activated T cells to elicit T-cell and B-cell effector functions (molecular mimicry).

TISSUE INJURY AND REPAIR

JANE E. SALMON

THE INFLAMMATORY RESPONSE: INNATE IMMUNE MECHANISMS

Inflammation is a vital physiologic response triggered by noxious agents that challenge homeostasis of the body. The innate immune system provides the first level of defense against signals of danger, including pathogenic microorganisms and sterile incursions such as trauma, cancer, ischemia, and metabolic perturbations. Host defense mechanisms generate a rapid protective response, render pathogens harmless, and repair damaged tissue. These highly controlled responses normally protect against further injury, but pathologic inflammation can be inappropriately triggered or inadequately controlled and, in some cases, lead to marked destruction of the extracellular matrix as well as to organ dysfunction.

Invading pathogens or environmental stresses stimulate tissue resident cells by engaging receptors that activate innate immunity. Innate immune responses are also required to initiate specific adaptive immune responses. Designed for rapid responses (minutes to hours), innate immunity relies on the body's ability to recognize conserved features that are present in pathogens but not in the uninfected host. Common motifs trigger innate immune responses, in contrast to the exquisite antigen specificity and precision of adaptive responses, which are slow to develop (days to weeks; Chapter 35).

An adaptive immune response is essential for host protection when innate mechanisms fail to contain the pathogen or injury.

INITIATORS AND EFFECTORS

Triggers of an innate inflammatory response can be classified as pathogen-associated molecular patterns (PAMPs), conserved molecular motifs of infectious agents, and damage-associated molecular patterns (DAMPs), which are signals of host cellular distress. A variety of pattern recognition receptors and cells of innate and adaptive immunity sense PAMPs and DAMPs. PAMP receptors, such as toll-like receptor (TLR) proteins, that are expressed on the cell surface or the inner leaflet of cytoplasmic vesicles, serve as sentinels that rapidly activate innate immune responses, thereby protecting the host from infection. DAMP recognition receptors within the cytoplasm sense "danger" signals that originate from stress, whether toxic environmental (e.g., urate) or cellular (e.g., adenosine triphosphate [ATP]), and respond to microenvironmental damage. Tissue injury induced by trauma or noxious stimuli triggers DAMP receptors to initiate inflammatory responses, thereby leading to microvascular damage, extravasation of leukocytes, and leakage of plasma proteins into the tissue (Fig. 36-1).

Upon encountering a pathogenic agent or tissue injury, the innate immune system is challenged to integrate multiple signals to initiate a proper protective response. Inflammasomes are cytoplasmic multiprotein complexes that comprise a sensor protein, inflammatory caspases, and, in some cases, an adapter protein that connects the two. Inflammasomes (Chapter 35) constitute fundamental processing units that contribute to PAMP and DAMP sensing and coordinate downstream signaling. Inflammasomes are activated by a range of endogenous and exogenous stimuli, thereby leading to enzymatic activation of a caspase and resulting in secretion of interleukin-1β (IL-1β) and IL-18, as well as apoptotic and pyroptotic cell death.

Resident tissue cells, mainly macrophages, dendritic cells, eosinophils, and mast cells that are activated by pattern recognition receptors, are the initiators of acute inflammation. These cells express surface or cytoplasmic pattern recognition receptors and, at the onset of an infection or other injury, they are activated and release inflammatory mediators that are responsible for the clinical signs of inflammation and tissue damage (see Fig. 36-1). Chemical factors produced during inflammation, including histamine, bradykinin, serotonin, leukotrienes, and prostaglandins, sensitize pain receptors, cause local vasodilation, and attract phagocytes, especially neutrophils. Neutrophils help to eliminate microbes but also can damage tissues owing to phagocytosis, the generation of reactive oxygen species, and degranulation, which releases proteases. Neutrophils also extrude chromatin fibers that contain antimicrobial peptides and enzymes, called neutrophil extracellular traps (NETs),[1] and that immobilize and kill invading

Hyperstimulation of T cells (e.g., by high doses of antigen and high concentrations of IL-2) preferentially activates pro-apoptotic pathways and causes elimination of the responding T-cell specificity. Clonal ignorance is defined as the presence of self-reactive lymphocytes that fail to recognize or respond to peripheral antigens. These cells remain responsive to antigenic challenge if given in the right setting. An example of clonal ignorance is nonresponsiveness to sequestered antigens that are not accessible to the immune system. Treg cells play a pivotal role in maintaining peripheral tolerance. Harnessing the frequencies and function of Foxp3 $CD4^+$ T cells may offer a promising approach to restoring peripheral tolerance in treating autoimmune diseases or facilitating transplantation tolerance.

A critically important mechanism of peripheral B tolerance is maintained through the absence of T-cell help. B lymphocytes that recognize self-antigens in the periphery in the absence of T-cell help are rendered anergic or are unable to enter lymphoid follicles, where they could receive T-cell help, effectively excluding them from immune responses.

CONTRIBUTION OF THE INNATE AND ADAPTIVE IMMUNE RESPONSES TO PATHOGENESIS OF DISEASE

Immunodeficiency and Autoimmunity

Characterization of genetic polymorphisms and mutations in immune system genes that are associated either with apparent vulnerability to infection or inappropriate self-reactivity and autoimmunity has provided important insights into immune mechanisms that are essential for host defense and maintenance of immune tolerance. Mutations in components of innate and adaptive immune system pathways that recognize, respond to, or regulate the response to viruses or bacteria characterize immunodeficiencies that can be life-threatening (see Chapter 231).[29] In some cases, those vulnerabilities are revealed only in the setting of an infection with an agent not previously encountered. For example, recent reports describe previously healthy men who developed severe disease in the setting of severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2) infection and were found to have mutations in the *TLR7* gene, thereby impairing the type I IFN response.[30]

Autoimmune and inflammatory diseases occur in about 5% of the general population. The mechanisms that account for the generation of autoreactive T cells, responses directed to modified self-antigens, and the well-established associations of certain MHC alleles with autoimmune diseases are areas of active investigation.[31] Although many autoimmune diseases may result from failure of tolerance mechanisms or dysfunction of the regulatory pathways that control adaptive immune responses, excessive activation of an innate immune response can set the stage for a self-reactive T- or B-cell response. Polymorphisms in genes encoding components of innate immune signaling pathways can amplify an immune response, thereby resulting in increased and sustained production of type I IFN, IL-1, or TNF-α. Endogenous ligands with potential to activate Toll-like receptors can act as effective immune stimuli in the setting of a pro-inflammatory environment associated with oxidative or apoptotic cell damage. Alterations in degradation of endogenous RNA and DNA based on single-gene mutations can result in activation of cytosolic nucleic acid sensors, sustained type I IFN production, skin lesions, and central nervous system involvement in diseases termed type I interferonopathies.[32] The inflammasome and its component proteins, including the NOD-like receptors, are recognized as mediators of inflammatory responses induced in some autoinflammatory syndromes (Chapter 240).

Many models of autoimmunity rely on the hypothesis that peripheral anergy is broken. Microbial infection or bacterial components in the gut microbiome (Chapter 257) may trigger an immune response that primes the immune system for an exaggerated and self-directed response to a subsequent trigger through epigenetic modifications.[33] Autoreactive B cells that recognize self-antigen complexed with foreign antigen may result in activation of T cells specific for the foreign antigen that then provide help to B cells specific for the self-antigen. Tolerance mechanisms of anergy or clonal ignorance can fail if a foreign antigen is sufficiently different from a self-antigen to initiate an immune response but sufficiently similar for activated T cells to elicit T-cell and B-cell effector functions (molecular mimicry).

TISSUE INJURY AND REPAIR

JANE E. SALMON

THE INFLAMMATORY RESPONSE: INNATE IMMUNE MECHANISMS

Inflammation is a vital physiologic response triggered by noxious agents that challenge homeostasis of the body. The innate immune system provides the first level of defense against signals of danger, including pathogenic microorganisms and sterile incursions such as trauma, cancer, ischemia, and metabolic perturbations. Host defense mechanisms generate a rapid protective response, render pathogens harmless, and repair damaged tissue. These highly controlled responses normally protect against further injury, but pathologic inflammation can be inappropriately triggered or inadequately controlled and, in some cases, lead to marked destruction of the extracellular matrix as well as to organ dysfunction.

Invading pathogens or environmental stresses stimulate tissue resident cells by engaging receptors that activate innate immunity. Innate immune responses are also required to initiate specific adaptive immune responses. Designed for rapid responses (minutes to hours), innate immunity relies on the body's ability to recognize conserved features that are present in pathogens but not in the uninfected host. Common motifs trigger innate immune responses, in contrast to the exquisite antigen specificity and precision of adaptive responses, which are slow to develop (days to weeks; Chapter 35).

An adaptive immune response is essential for host protection when innate mechanisms fail to contain the pathogen or injury.

INITIATORS AND EFFECTORS

Triggers of an innate inflammatory response can be classified as pathogen-associated molecular patterns (PAMPs), conserved molecular motifs of infectious agents, and damage-associated molecular patterns (DAMPs), which are signals of host cellular distress. A variety of pattern recognition receptors and cells of innate and adaptive immunity sense PAMPs and DAMPs. PAMP receptors, such as toll-like receptor (TLR) proteins, that are expressed on the cell surface or the inner leaflet of cytoplasmic vesicles, serve as sentinels that rapidly activate innate immune responses, thereby protecting the host from infection. DAMP recognition receptors within the cytoplasm sense "danger" signals that originate from stress, whether toxic environmental (e.g., urate) or cellular (e.g., adenosine triphosphate [ATP]), and respond to microenvironmental damage. Tissue injury induced by trauma or noxious stimuli triggers DAMP receptors to initiate inflammatory responses, thereby leading to microvascular damage, extravasation of leukocytes, and leakage of plasma proteins into the tissue (Fig. 36-1).

Upon encountering a pathogenic agent or tissue injury, the innate immune system is challenged to integrate multiple signals to initiate a proper protective response. Inflammasomes are cytoplasmic multiprotein complexes that comprise a sensor protein, inflammatory caspases, and, in some cases, an adapter protein that connects the two. Inflammasomes (Chapter 35) constitute fundamental processing units that contribute to PAMP and DAMP sensing and coordinate downstream signaling. Inflammasomes are activated by a range of endogenous and exogenous stimuli, thereby leading to enzymatic activation of a caspase and resulting in secretion of interleukin-1β (IL-1β) and IL-18, as well as apoptotic and pyroptotic cell death.

Resident tissue cells, mainly macrophages, dendritic cells, eosinophils, and mast cells that are activated by pattern recognition receptors, are the initiators of acute inflammation. These cells express surface or cytoplasmic pattern recognition receptors and, at the onset of an infection or other injury, they are activated and release inflammatory mediators that are responsible for the clinical signs of inflammation and tissue damage (see Fig. 36-1). Chemical factors produced during inflammation, including histamine, bradykinin, serotonin, leukotrienes, and prostaglandins, sensitize pain receptors, cause local vasodilation, and attract phagocytes, especially neutrophils. Neutrophils help to eliminate microbes but also can damage tissues owing to phagocytosis, the generation of reactive oxygen species, and degranulation, which releases proteases. Neutrophils also extrude chromatin fibers that contain antimicrobial peptides and enzymes, called neutrophil extracellular traps (NETs),[1] and that immobilize and kill invading

ABSTRACT

Many clinically important diseases are characterized by normal immune responses directed against an inappropriate antigen, typically in the absence of infection. Hypersensitivity reactions are overreactions of the immune system to innocuous environmental antigens. The four types of hypersensitivity reactions are distinguished by the effector responses mediated by immunologic mechanisms that cause tissue damage. Types I to III are antibody mediated and are distinguished by the different types of antigens recognized and different classes of antibodies involved. Receptors for Ig (Fc receptors) play a crucial role in triggering the effector functions. Type I is mediated by IgE, which induces mast cell activation, whereas types II and III are mediated by IgG, which can engage phagocyte activation and complement activation, depending upon the antigens and antibody subclasses involved. Type II reactions are directed against cell surface or matrix antigens, whereas type III reactions are directed against soluble antigens. Damage to cells and tissues is caused by responses triggered by immune complexes. Type IV hypersensitivity reactions are T cell mediated. The means of antigen recognition that lead to tissue damage in autoimmune disease are similar to the mechanisms elicited in response to pathogens and environmental antigens, and the effector mechanisms of autoimmunity resemble those causing some types of hypersensitivity reactions.

microorganisms. NETs also may contribute to autoimmunity by binding to and presenting extracellular autoantigens or by stimulating thrombus formation. Neutrophils trigger other parts of the immune system by releasing factors that summon additional leukocytes and lymphocytes.

Local activation of the innate immune response quickly triggers a variety of signals that recruit other inflammatory cells (see Fig. 36-1). Resident vascular endothelial cells, mast cells, dendritic cells, and interstitial fibroblasts also release soluble mediators, including eicosanoids, chemokines, and pro-inflammatory cytokines. Pro-inflammatory members of the IL-1 family (IL-1α, IL-1β, IL-18, and IL-33) and tumor necrosis factor-α (TNF-α) have pleiotropic activities; they enhance adhesion molecule expression on endothelial cells, induce proliferation of endogenous cells, stimulate antigen presentation, and amplify the inflammatory response. Newly arrived inflammatory cells and locally stimulated cells also produce reactive toxic intermediates plus a variety of proteases (e.g., matrix metalloproteinases, serine proteases, and cysteine proteases). Enzymes that degrade the extracellular matrix regulate inflammatory tissue turnover, thereby damaging tissue, releasing matrix-bound growth factors and cytokines, and promoting the retention of newly recruited cells. In most situations, the normal physiologic response is an exquisitely coordinated program that uses proteolytic enzymes to remodel the extracellular matrix and promote a supportive environment for wound healing rather than tissue damage.

THE INFLAMMATORY RESPONSE: ADAPTIVE IMMUNE MECHANISMS

The adaptive immune response is a crucial component of host defense against infection, but unlike the innate response, it is learned rather than intrinsic. Its distinguishing and unique feature is the ability to recognize pathogens specifically, based on clonal selection of lymphocytes bearing antigen-specific receptors. Effector mechanisms that eliminate pathogens in adaptive immune responses are essentially identical to those of innate immunity. The specific antigen recognition feature of the adaptive immune response seems to have been appended to the preexisting innate defense system. As a result, the inflammatory cells and molecules of the innate immune system are essential for the effector functions of B and T lymphocytes.

In addition to initiating protective responses, antigens unassociated with infectious agents also may elicit adaptive immune responses. Many clinically important diseases are characterized by normal immune responses directed against an inappropriate antigen, typically in the absence of infection. Immune responses directed at noninfectious antigens occur in allergy and hypersensitivity, in which the antigen is an innocuous foreign substance, and in autoimmunity, in which the response is to a self-antigen. Adaptive immune responses mediate tissue injury in allergy, hypersensitivity, and autoimmunity.

INITIATORS AND EFFECTORS

Effector actions of antibodies depend on recruiting cells and molecules of the innate immune system. Antibodies are adapters that bind antigens to nonspecific inflammatory cells and direct their destructive effector responses. Antibodies also activate the complement system (Chapter 37), which enhances opsonization of antigens, recruits phagocytic cells, and amplifies (or "complements") antibody-triggered damage. The isotype or class of antibodies produced determines which effector mechanisms are engaged.

Cell-bound receptors for immunoglobulin (Ig) constitute the link between humoral and cellular aspects of the immune cascade and play an integral part in the process by which foreign and endogenous opsonized material is identified and destroyed. These cell-based binding sites for antibodies, termed *Fc receptors,* interact with the constant region (Fc portion) of the immunoglobulin heavy chain of a particular antibody class regardless of its antigen specificity. Accessory cells that lack intrinsic specificity, such as neutrophils, macrophages, and mast cells, are recruited to participate in inflammatory responses through the interaction of their Fc receptors with antigen-specific antibodies. Distinct receptors for different immunoglobulin isotypes are expressed on different effector cells.

Receptors for IgG (FcγRs) are a diverse group of receptors expressed as hematopoietic cell surface molecules on phagocytes (macrophages, monocytes, neutrophils), platelets, mast cells, eosinophils, and natural killer (NK) cells.[2] FcγRs often are expressed as stimulatory and inhibitory pairs. Triggering of stimulatory FcγRs initiates a series of events, including phagocytosis; antibody-dependent, cell-mediated cytotoxicity; secretion of granules; and release of inflammatory mediators, such as cytokines, reactive oxidants, and proteases. Extensive structural diversity among FcγR family members leads to differences in binding capacity, signal transduction pathways, and cell type–specific expression patterns. The structure of the Fc domain of IgG dictates interactions with FcγRs and can lead to pro- or anti-inflammatory responses. The strength of interactions between immune complexes and various FcγRs is determined by structural diversity within IgG subclasses (IgG1, IgG2, IgG3, IgG4) and post-translational modifications of their Fc domains.[3] This diversity allows IgG complexes to activate a broad program of cell functions relevant to inflammation, host defense, and autoimmunity. Phagocyte activation is triggered by stimulatory FcγRs, facilitating the recognition, uptake, and destruction of antibody-coated targets, whereas multivalent IgG binding to FcγRs on platelets leads to platelet aggregation and thrombosis, and binding to FcγRs on NK cells mediates cytotoxicity of antibody-coated targets.

IgE binds to high-affinity FcεRs on mast cells, basophils, and activated eosinophils.[4] In contrast to FcγRs, which are low affinity and bind to multivalent IgG rather than circulating individual IgG molecules, FcεRs can bind monomeric IgE. A single mast cell may be armed with IgE molecules specific for different

antigens, all bound to surface FcεRs. Mast cells, localized beneath the mucosa of the gastrointestinal and respiratory tracts and the dermis of the skin, await exposure to multivalent antigens, which cross-link surface IgE bound to FcεRs and cause release of histamine-containing granules and generation of cytokines and other inflammatory mediators (Chapter 235). IgE-mediated activation of eosinophils, which are normally present in the connective tissue of underlying respiratory, urogenital, and gut epithelium, leads to the release of highly toxic granule proteins, free radicals, and chemical mediators such as prostaglandins, cytokines, and chemokines (Chapter 156). These mediators amplify local inflammatory responses by activating endothelial cells and recruiting and activating more eosinophils and leukocytes. Prepackaged granules and high-affinity FcεRs that bind to free monomeric IgE enable an immediate response to pathogens or allergens at the first site of entry, a location where FcεR-bearing cells reside.

Inhibitory FcγRs, which modulate activation thresholds and terminate stimulating signals, are key elements in the regulation of effector function. Given that inhibitory and stimulatory Fc receptors are often coexpressed on the same cells, the effector response to a specific stimulus in a particular cell represents the balance between stimulatory and inhibitory signals. Inhibitory FcγRs can dampen responses triggered by FcεRs on mast cells and FcγR-mediated inflammation at sites of immune complex deposition.

Effector activities targeted by IgG and IgM also may be mediated by components of the complement system (Chapter 37). Antigen-bound multimeric immunoglobulin can initiate activation of the classic pathway of complement, causing enhanced phagocytosis of antigen-antibody complexes, increased local vascular permeability, and recruitment and activation of inflammatory cells. The target of injury is specified by the antibody, and the extent of damage is determined by the synergistic activities of immunoglobulin and complement.

Antigen-specific effector T cells also may initiate tissue injury. On exposure to an appropriate antigen, memory T cells are stimulated to release cytokines and chemokines that activate local endothelial cells and recruit and activate macrophages and other inflammatory cells. The effector cells directed by T-cell-derived cytokines, or cytolytic T cells themselves, mediate tissue damage. T helper 1 (T_H1) cells produce interferon-γ (IFN-γ) and activate macrophages to cause injury, whereas T_H2 cells produce IL-4, IL-5, and eotaxin (an eosinophil-specific chemokine) and trigger inflammatory responses in which eosinophils predominate. T_H17 cells secrete several effector molecules, including IL-17, which act on both immune and nonimmune cells to trigger differentiation; release of antimicrobial molecules, cytokines, and chemokines; and recruitment to sites of inflammation.[5] T_H effector subsets, more recently identified, include follicular T helper cells (T_{FH}), which provide help to B cells in germinal centers and thus are key regulators of humoral responses and antibody production.

HYPERSENSITIVITY REACTIONS

In predisposed individuals, innocuous environmental antigens may stimulate an adaptive immune response, immunologic memory, and, on subsequent exposure to the antigen, inflammation. Damage to epithelial surfaces lies at the origin of various manifestations of allergic disease. The epithelium of the lungs, gut, and skin are sensors of environmental stimuli, and alterations to their epithelial surfaces drives a type 2 immune response that underlies atopic diseases.[6] These "overreactions" of the immune system to harmless environmental antigens (allergens), called *hypersensitivity* or *allergic reactions* (Chapter 230), produce tissue injury and can cause serious disease. Hypersensitivity reactions are grouped into four types according to the effector mechanisms by which they are produced (Table 36-1). The effectors for types I, II, and III hypersensitivity reactions are antibody molecules, whereas type IV reactions are mediated by antigen-specific effector T cells.

Autoimmune disease is characterized by the presence of antibodies and T cells specific for self-antigens expressed on target tissues. The mechanisms of antigen recognition and effector function that lead to tissue damage in autoimmune disease are similar to the mechanisms elicited in response to pathogens and environmental antigens. These mechanisms resemble certain hypersensitivity reactions and may be classified accordingly. Autoimmune disease caused by antibodies directed against cell surface or extracellular matrix antigens corresponds to type II hypersensitivity reactions; disease caused by formation of soluble immune complexes that subsequently are deposited in tissue corresponds to type III hypersensitivity; and disease caused by effector T cells corresponds to type IV hypersensitivity. Typically, several of these pathogenic mechanisms are operative in autoimmune disease. However, IgE responses are not associated with damage in autoimmunity.

Type I Hypersensitivity Reactions

Type I hypersensitivity reactions (Fig. 36-2) are triggered by the interaction of antigen with antigen-specific IgE bound to FcεRs on mast cells, which causes mast cell activation. Proteolytic enzymes and toxic mediators, such as histamine, are released immediately from preformed granules, and chemokines, cytokines, and leukotrienes are synthesized after activation. Together, these mediators increase vascular permeability, break down tissue matrix proteins, promote eosinophil production and activation (IL-3, IL-5, and granulocyte-macrophage colony-stimulating factor [GM-CSF]), and cause influx of effector leukocytes (TNF-α, platelet-activating factor, and macrophage inflammatory protein [MIP-1]), constriction of smooth muscle, stimulation of mucus secretion, and amplification of T_H2 cell responses (IL-4 and IL-13). Eosinophils and basophils, which are activated through cell surface FcεRs, rapidly release highly toxic granular proteins (major basic protein, eosinophil peroxidase, and collagenase) and, over a longer period, produce cytokines (IL-3, IL-5, and GM-CSF), chemokines (IL-8), prostaglandins, and leukotrienes that activate epithelial cells, leukocytes, and eosinophils to augment local inflammation and tissue damage.

FcεR-bearing effectors act in a coordinated fashion. The immediate allergic inflammatory reaction initiated by mast cell products is followed by a late-phase response that involves recruitment and activation of eosinophils, basophils, and T_H2 lymphocytes. The manifestations of IgE-mediated reactions depend on

TABLE 36-1 FOUR MAJOR TYPES OF IMMUNOLOGICALLY MEDIATED HYPERSENSITIVITY REACTIONS*

IMMUNOLOGIC SPECIFICITY	TYPE I (IgE ANTIBODY)	TYPE II (IgG ANTIBODY)	TYPE III (IgG ANTIBODY)	TYPE IV (T CELLS)			
				T_H1 CELLS	T_H2 CELLS	T_H17 CELLS	T CELLS
Antigen	Soluble antigen allergen	Cell- or matrix-associated antigen	Soluble antigen	Soluble antigen	Soluble antigen	Soluble antigen	Cell-associated antigen
Effector mechanism	FcεRI- or FcγRIII-dependent mast cell activation, with release of mediators/cytokines	$Fc\gamma R^+$ cells (phagocytes, NK cells), complement	$Fc\gamma R^+$ cells, complement	Macrophage activation	Eosinophil activation	Macrophage activation, neutrophil activation	Direct cytotoxicity
Examples	Systemic anaphylaxis, asthma, allergic rhinitis, urticaria, angioedema	Certain drug reactions and reactions to incompatible blood transfusions	Arthus reaction and other immune complex–mediated reactions (e.g., serum sickness, subacute bacterial endocarditis)	Contact dermatitis, tuberculin reaction	Chronic allergic inflammation (e.g., chronic asthma, chronic allergic rhinitis)	Contact dermatitis, atopic dermatitis, asthma, rheumatoid arthritis	Contact dermatitis (e.g., poison ivy), reactions to certain virus-infected cells, some instances of graft rejection

*Hypersensitivity reactions were classified into four types by Coombs and Gell (1963) and modified by Janeway and colleagues (2001).
FcγR = Fc receptor for immunoglobulin G; FcεR = Fc receptor for immunoglobulin E; Ig = immunoglobulin; NK = natural killer.
From Coombs RRA, Gell PGH. Classification of allergic reactions responsible for clinical hypersensitivity and disease. In: Gell PGH, Coombs RA, eds. *Clinical Aspects of Immunology*. Oxford, UK: Blackwell; 1963; and Janeway C, Travers P, Walport M, Shlomchick M. *Immunobiology: The Immune System in Health and Disease*. 5th ed. New York: Garland Publishing; 2001.

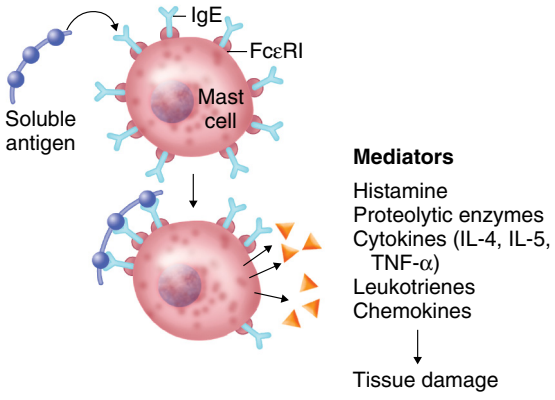

FIGURE 36-2. Type I hypersensitivity. Type I responses are mediated by immunoglobulin E (IgE), which induces mast cell activation. Cross-linking of the Fc receptor for IgE (FcεR) on mast cells, triggered by the interaction of multivalent antigen with antigen-specific IgE bound to FcεR, causes the release of preformed granules containing histamine and proteases. Cytokines, chemokines, and lipid mediators are synthesized after cell activation. IL = interleukin; TNF = tumor necrosis factor.

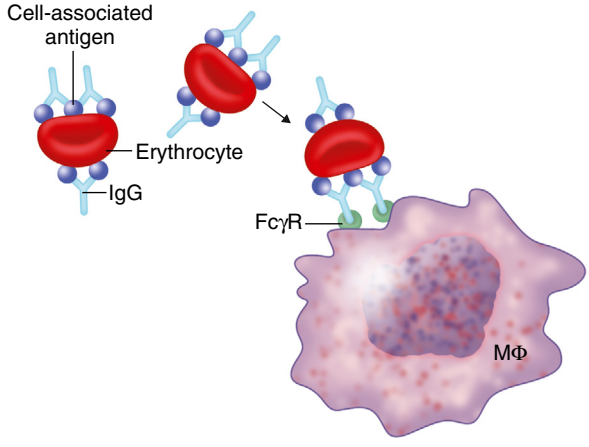

FIGURE 36-3. Type II hypersensitivity. Type II responses are mediated by immunoglobulin G (IgG) directed against cell surface or matrix antigens, which initiates effector responses through the Fc receptor for IgG (FcγR) and complement. The relative contributions of these pathways vary with the IgG subclass and the nature of the antigen. Only FcγR-mediated phagocytosis by macrophages (MΦ) is depicted in this figure. Activation of complement components would result in binding of C3b to the red blood cell membrane, rendering red blood cells susceptible to phagocytosis and leading to formation of the membrane attack complex and cell lysis.

the site of mast cell activation. Mast cells reside in vascular and epithelial tissue throughout the body. In a sensitized host (an individual with IgE responses to antigens), re-exposure to antigen leads to type I hypersensitivity responses only in the mast cells exposed to the antigen. Inhalation of antigens produces bronchoconstriction and increased mucus secretion (asthma and allergic rhinitis); ingestion of antigens causes increased peristalsis and secretion (diarrhea and vomiting); and the presence of subcutaneous antigens initiates increased vascular permeability and swelling (urticaria and angioedema). Blood-borne antigens cause systemic mast cell activation, increased capillary permeability, hypotension, tissue swelling, and smooth muscle contraction—the characteristics of systemic anaphylaxis.[7]

Type II Hypersensitivity Reactions

Type II hypersensitivity reactions (Fig. 36-3) are caused by chemical modification of cell surface or matrix-associated antigens that generates "foreign" epitopes to which the immune system is not tolerant. B cells respond to this antigenic challenge by producing IgG, which binds to these modified cells and renders them susceptible to destruction through complement activation, phagocytosis, and antibody-dependent cytotoxicity This phenomenon is seen clinically when drugs interact with blood constituents and alter their cellular antigens. Hemolytic anemia caused by immune-mediated destruction of erythrocytes (Chapter 146) and thrombocytopenia caused by destruction of platelets (Chapter 158), both type II hypersensitivity reactions, are adverse effects of certain drugs. Chemically reactive drug molecules bind covalently to the surface of red cells or platelets creating new epitopes that in a small subset of individuals are recognized as foreign antigens by the immune system and stimulate production of IgM and IgG antibodies reactive with the conjugate of drug and cell surface protein. Penicillin-specific IgG binds to penicillin-modified proteins on red blood cells and triggers activation of the complement cascade. Activation of complement components C1 through C3 results in covalent binding of C3b to the red cell membrane and renders circulating red cells susceptible to phagocytosis by FcγR and complement receptor–bearing macrophages in the spleen or liver. Activation of complement components C1 through C9 and formation of the membrane attack complex cause intravascular lysis of red cells. The factors that predispose only some people to drug-induced type II hypersensitivity reactions are unknown. Penicillin, quinidine, and methyldopa have been associated with hemolytic anemia and thrombocytopenia through this mechanism. Another example is heparin-induced thrombocytopenia or thrombosis, a severe, life-threatening complication that occurs in 1 to 3% of patients exposed to heparin (Chapter 158). Interactions among heparin, human platelet factor 4, antibodies to the human platelet factor 4–heparin complex, platelet FcγRIIA, and splenic FcγRs (which remove opsonized platelets) are involved in the pathogenesis of this disease.

Autoantibodies directed at antigens on the cell surface or extracellular matrix cause tissue damage by mechanisms similar to type II hypersensitivity reactions. IgG or IgM antibodies against erythrocytes lead to cell destruction in autoimmune hemolytic anemia because opsonized cells (coated with IgG or IgM and complement) are removed from the circulation by phagocytes in the liver and spleen or are lysed by formation of the membrane attack complex. Platelet destruction in autoimmune thrombocytopenic purpura occurs through a similar process. Because nucleated cells express membrane-bound complement regulatory proteins, they are less sensitive to lysis through the membrane attack complex, but when coated with antibody, they become targets for phagocytosis or antibody-dependent cytotoxicity. This mechanism is responsible for autoimmune and alloimmune neutropenia (Chapter 153).

IgM and IgG antibodies recognizing antigens within tissue or binding to extracellular antigens cause local inflammatory damage through FcγR and complement mechanisms.[8] Pemphigus vulgaris (Chapter 406) is a serious blistering disease that results from a loss of adhesion between keratinocytes caused by autoantibodies against the extracellular portions of desmoglein 3, an intercellular adhesion structure of epidermal keratinocytes. Another example of a type II hypersensitivity reaction is Goodpasture disease (Chapter 79), in which antibodies against the α_3-chain of type IV collagen (the collagen in basement membranes) are deposited in glomerular and lung basement membrane. Tissue-bound autoantibodies activate monocytes, neutrophils, and basophils through FcγRs, initiating release of proteases, reactive oxidants, cytokines, and prostaglandins. Local activation of complement, particularly C5a, recruits and activates inflammatory cells and amplifies tissue injury. Neighboring cells are lysed by assembly of the membrane attack complex or by FcγR-initiated, antibody-dependent cytotoxicity.

Autoantibodies against cell surface receptors produce disease by stimulating or blocking receptor function. In myasthenia gravis (Chapter 390), autoantibodies against the acetylcholine receptors on skeletal muscle cells bind the receptor and induce its internalization and degradation in lysosomes, thereby reducing the efficiency of neuromuscular transmission and causing progressive muscle weakness. In contrast, Graves disease (Chapter 207) is characterized by autoantibodies that act as agonists. Autoantibodies to thyroid-stimulating hormone receptors bind the receptor, mimicking the natural ligand, inducing thyroid hormone overproduction, disrupting feedback regulation, and causing hyperthyroidism.

Type III Hypersensitivity Reactions

Type III hypersensitivity reactions (Fig. 36-4) are caused by tissue deposition of small soluble immune complexes that contain antigens and high-affinity IgG antibodies directed at these antigens. Localized deposition of immune complexes activates FcγR-bearing mast cells and phagocytes and initiates the complement cascade, all effectors of tissue damage.

Immune complexes are generated in all antibody responses. The formation and the fate of immune complexes depend on the biophysical and immunologic properties of the antigen and the antibody. Larger aggregates fix complement more efficiently, present a broader multivalent array of ligands for complement and FcγRs to bind, and are taken up more readily by mononuclear phagocytes in the liver and spleen and thereby removed from the circulation. Smaller immune complexes, which form in antigen excess—as occurs early in an immune response—circulate in the blood and are deposited in blood

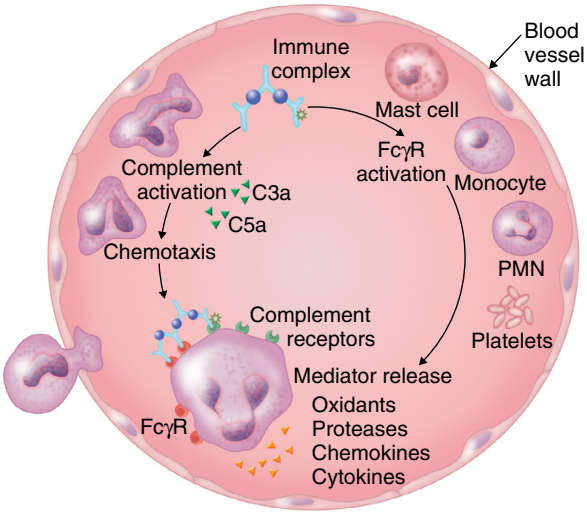

FIGURE 36-4. Type III hypersensitivity. Type III responses are mediated by immunoglobulin G (IgG) directed against soluble antigens. Localized deposition of immune complexes activates mast cells, monocytes, neutrophils, and platelets bearing the Fc receptor for IgG (FcγR), and initiates the complement cascade, all effectors of tissue damage. Generation of complement activation products C3a and C5a recruits and stimulates inflammatory cells and amplifies effector functions. PMN = polymorphonuclear leukocyte (also called *neutrophil*).

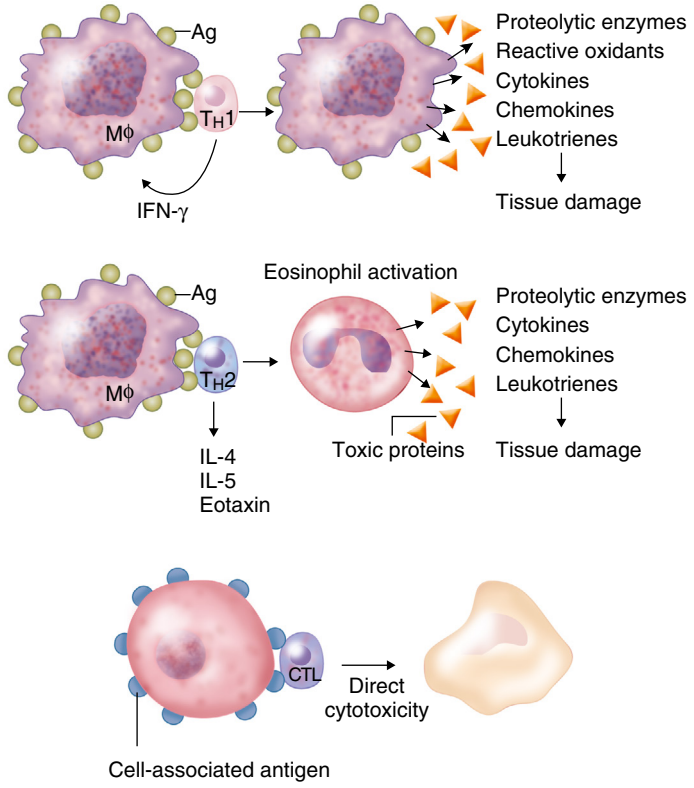

FIGURE 36-5. Type IV hypersensitivity. Type IV responses are mediated by T cells through three different pathways. In the first, type 1 helper T (T_H1) cells recognize soluble antigens (Ag) and release interferon-γ (IFN-γ) to activate effector cells, in this case macrophages (MΦ), and cause tissue injury. In T_H2-mediated responses, eosinophils predominate. T_H2 cells produce cytokines to recruit and activate eosinophils, leading to their degranulation and tissue injury. In the third pathway, damage is caused directly by cytolytic T lymphocytes (CTL). IL = interleukin.

vessels, where they initiate inflammatory reactions and tissue damage through interactions with FcγRs and complement receptors.

Serum sickness (Chapter 230)[9] is a systemic type III hypersensitivity reaction, historically described in patients injected with therapeutic horse antiserum for the treatment of bacterial infections. In general, serum sickness occurs after the injection of large quantities of a soluble antigen. Clinical features include chills, fever, rash, urticaria, arthritis, and glomerulonephritis. Disease manifestations become evident 7 to 10 days after exposure to the antigen, when antibodies are generated against the foreign protein and form immune complexes with these circulating antigens. Immune complexes are deposited in blood vessels, where they activate phagocytes and complement, producing widespread tissue injury and clinical symptoms. The effects are transient, however, and resolve after the antigen is cleared.

A syndrome similar to serum sickness occurs in chronic infections in which pathogens persist in the face of continued immune response. In subacute bacterial endocarditis (Chapter 61), antibody production continues but fails to eliminate the infecting microbes. As the pathogens multiply, generating new antigens, immune complexes form in the circulation and are deposited in small blood vessels, where they lead to inflammatory damage of skin, kidney, and nerve. Hepatitis B virus infection (Chapters 134 and 135) may be associated with immune complex deposition early in its course, during a period of antigen excess, because antibody production in response to hepatitis B surface antigen is as yet relatively insufficient; some anicteric patients may present with acute arthritis. Mixed essential cryoglobulinemia, which may be associated with hepatitis C viral infection (Chapters 134 and 135), is an immune complex–mediated vasculitis in which deposition of complexes containing IgG, IgM, and hepatitis C antigens causes inflammation in peripheral nerves, kidneys, and skin. Serum sickness also can develop in transplant recipients who are treated with mouse monoclonal antibodies specific for human T cells to prevent rejection, and in patients with myocardial infarction who are treated with the bacterial enzyme streptokinase to effect thrombolysis.

Systemic lupus erythematosus (Chapter 245), the prototypical immune complex–mediated autoimmune disease, is characterized by circulating IgG directed against common cellular constituents, typically DNA and DNA-binding proteins. Small immune complexes are deposited in skin, joints, and glomeruli and initiate local tissue damage.

Type IV Hypersensitivity Reactions

Type IV hypersensitivity reactions (Fig. 36-5), also known as *delayed-type hypersensitivity reactions*, are mediated by antigen-specific effector T cells.[10] These reactions are distinguished from other hypersensitivity reactions by the lag time from exposure to the antigen until the response is evident (1 to 3 days). Antigen is taken up, processed, and presented by macrophages or dendritic cells. T_H1 effector cells that recognize the specific antigen (these are scarce and take time to arrive) are stimulated to release chemokines, which recruit macrophages to the site, release cytokines that mediate tissue injury and growth factors that stimulate monocyte production. IFN-γ activates macrophages and enhances their release of inflammatory mediators, whereas TNF-α and TNF-β activate endothelial cells, enhance vascular permeability, and damage local tissue. The prototypical type IV hypersensitivity reaction is the tuberculin test, but similar reactions can occur after contact with sensitizing antigens (e.g., poison ivy, certain metals) and lead to epidermal reactions characterized by erythema, cellular infiltration, and vesicles. $CD8^+$ T cells also may mediate damage by direct toxicity.

In contrast to T_H1-mediated hypersensitivity reactions, in which the effectors are macrophages, eosinophils predominate in T_H2-mediated responses. T_H2 effector T cells are associated with tissue damage in chronic asthma (Chapter 75). T_H2 cells produce cytokines to recruit and activate eosinophils (IL-5 and eotaxin), leading to degranulation, further tissue injury, and chronic, irreversible airway damage.

Additional T_H effector cells, such as T_H17 cells, mediate tissue damage. T_H17 cells produce IL-17 family cytokines, as well as IL-21, IL-22, and GM-CSF, that regulate innate effectors and orchestrate local inflammation by inducing release of pro-inflammatory cytokines and chemokines, proliferation and activation of effector cells and other target cells, recruitment of neutrophils, and enhanced T_H2-mediated inflammation, all of which amplify allergic and autoimmune responses. T_H17 cells have been implicated in allergic disorders (atopic dermatitis, asthma) and autoimmune and inflammatory diseases (psoriasis, inflammatory bowel disease, rheumatoid arthritis, systemic lupus erythematosus, multiple sclerosis), and chronic transplant rejection.

In some autoimmune diseases, effector T cells specifically recognize self-antigens to cause tissue damage, either by direct cytotoxicity or by inflammatory responses mediated by activated macrophages. In type 1 insulin-dependent diabetes mellitus, T cells mediate destruction of β cells of the pancreatic islets. IFN-γ–producing T cells specific for myelin basic proteins have been implicated in multiple sclerosis. Rheumatoid arthritis (Chapter 243) is another autoimmune disease caused, at least in part, by activated T_H1 cells.

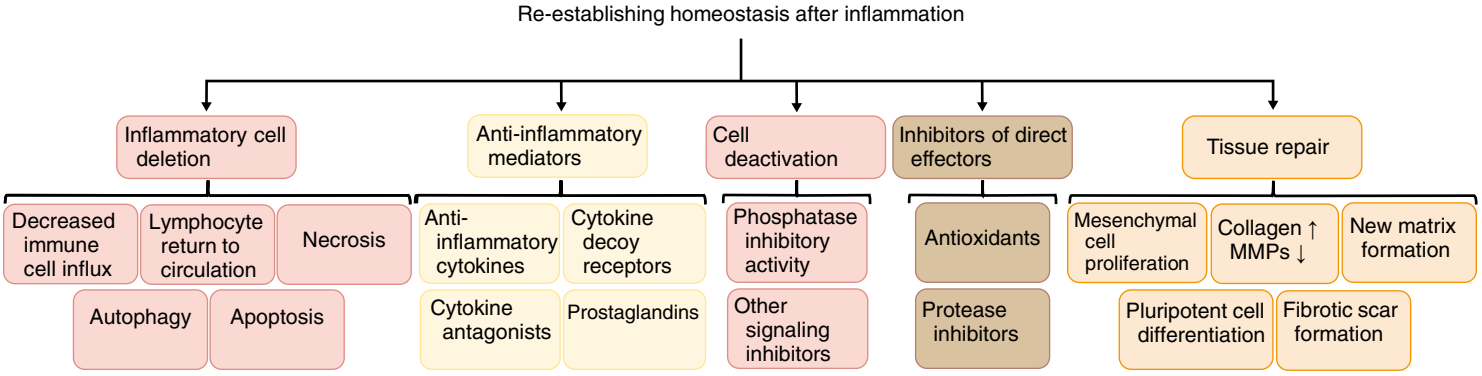

FIGURE 36-6. Mechanisms that resolve inflammation and lead to repair of the extracellular matrix. MMPs = matrix metalloproteinases.

TISSUE REPAIR AND RESOLUTION OF INFLAMMATION

Transient inflammation is a normal physiologic response, but serious injury results when unabated inflammation persists. After an inflammatory response is initiated, homeostasis must be reestablished by removing or deactivating mediators and effector cells, thereby permitting damaged tissues to repair. This resolution process requires cellular responses such as apoptosis and necrosis, the generation of anti-inflammatory cytokines and antioxidants, and the production of protease inhibitors (Fig. 36-6).

CELLULAR RESPONSES

Removal of inflammatory cells is accomplished by suppressing the production of chemotactic factor and the expression of vascular adhesion molecules, thereby releasing cells (particularly lymphocytes) from tissues so they can return to the circulation through the lymphatic system or by directly causing cell death via necrosis, apoptosis, or autophagy. However, the release of cellular contents by dying cells may be deleterious, and defective apoptosis or the persistence of apoptotic cells can contribute to chronic inflammation and to autoimmune diseases.

Some immune cells disappear during the resolution phase, whereas other cells expand.[11] For example, mesenchymal cells, such as fibroblasts, typically proliferate to produce new matrix, which in turn contracts to form fibrotic scar tissue. DNA synthesis in these stromal cells is induced by locally produced growth factors, such as platelet-derived growth factor. TGF-β stimulates fibroblasts to proliferate and changes their phenotype to healing by driving matrix formation through increased production of collagen and suppressed expression of matrix metalloproteinases. Mesenchymal stem cells also can differentiate into organ-specific lineages and, in the appropriate milieu, become bone cells, chondrocytes, adipocytes, or other terminally differentiated stromal cells.

SOLUBLE MEDIATORS AND INHIBITORS OF DAMAGING EFFECTORS

Resident and infiltrating cells release anti-inflammatory cytokines. TGF-β and IL-10 are produced by macrophages, interstitial fibroblasts, or T cells. T-cell cytokines (e.g., IL-4, IL-10, and IL-13) suppress the expression of matrix metalloproteinases by IL-1- or TNF-stimulated cells. TGF-β suppresses the production of collagenase, increases the deposition of collagen, and induces the tissue production of metalloproteinase inhibitors, thereby decreasing the activity of matrix metalloproteinases.

In addition, intracellular safety mechanisms regulate inflammatory signaling pathways to ensure that the process is self-limited. For example, kinases in growth factor receptors and other intracellular pathways activated by pro-inflammatory cytokines require phosphorylation to amplify enzyme activity, but phosphatases remove these phosphates so that kinases return to their resting inactive form.

Catalase and superoxide dismutase, which are antioxidant enzymes, inactivate toxic reactive oxygen intermediates released by phagocytes. The removal of toxic metabolites is facilitated by glutathione peroxidases and glutathione reductase.

Protease inhibitors are produced to regulate endogenous proteases and thereby to reduce the likelihood that collateral tissue damage will occur. For example, serine protease inhibitors (e.g., antithrombin III, plasminogen activator inhibitors 1 and 2, and α_1-antitrypsin) attenuate inflammation and resolve blood clots. Tissue inhibitors of metalloproteinases bind to activated matrix metalloproteinases and irreversibly block their catalytic sites to inhibit enzyme function. Examples of disease states characterized by an unfavorable balance between tissue inhibitors of metalloproteinases and matrix metalloproteinases include loss of cartilage in arthritis and progression of tumor metastases. Inhibition of pro-inflammatory cytokines and growth factors is associated with increased production of matrix protein and decreased activity of matrix metalloproteinases.

37 COMPLEMENT SYSTEM IN DISEASE

JOHN P. ATKINSON AND V. MICHAEL HOLERS

The complement system consists of plasma and membrane proteins that participate in host defense against infections and in clearance of cellular and extracellular debris, as well as in a wide variety of autoimmune and inflammatory states (Fig. 37-1).[1–3] Complement is essential in innate immunity and a potent effector arm of adaptive (humoral) immunity. It is a *first* responder, especially in blood, to bacterial and viral invasion (Table 37-1). It helps to maintain sterility ("guardian of the intravascular space") by depositing within seconds its opsonic and membrane-perturbing fragments on a pathogen's surface. A second major activity of complement is to promote the inflammatory response via the release of soluble fragments *(anaphylatoxins)* that act in both extracellular and intracellular sites. These fragments bind to their receptors, thereby leading to cellular activation, including chemokinesis and chemotaxis by phagocytic cells, and enhancing protection against infections. Furthermore, the deposition of complement fragments on immune complexes keeps them from precipitating and promotes their adherence to red blood cells (RBCs) for a hand-off to monocytes and dendritic cells in the liver and spleen.

Through these interactions, complement also instructs the adaptive immune response. Antigens decorated by complement proteins are more efficiently taken up by, or held in place for presentation to, monocytes, follicular-dendritic cells, B lymphocytes, and other antigen-presenting cells, thereby resulting in an adaptive immune response (Chapter 35). For example, complement activation is required for an optimal antibody response to most foreign antigens. In this way, the complement system is often called "nature's adjuvant." Individuals lacking a functional complement system are predisposed to bacterial infections, predominantly by encapsulated organisms, including streptococcus, staphylococcus, *Haemophilus* spp, and *Neisseria* spp. Surprisingly, a complete deficiency of C1q, which is an early component of the classical complement

37 COMPLEMENT SYSTEM IN DISEASE

JOHN P. ATKINSON AND V. MICHAEL HOLERS

The complement system consists of plasma and membrane proteins that participate in host defense against infections and in clearance of cellular and extracellular debris, as well as in a wide variety of autoimmune and inflammatory states (Fig. 37-1).[1–3] Complement is essential in innate immunity and a potent effector arm of adaptive (humoral) immunity. It is a *first* responder, especially in blood, to bacterial and viral invasion (Table 37-1). It helps to maintain sterility ("guardian of the intravascular space") by depositing within seconds its opsonic and membrane-perturbing fragments on a pathogen's surface. A second major activity of complement is to promote the inflammatory response via the release of soluble fragments *(anaphylatoxins)* that act in both extracellular and intracellular sites. These fragments bind to their receptors, thereby leading to cellular activation, including chemokinesis and chemotaxis by phagocytic cells, and enhancing protection against infections. Furthermore, the deposition of complement fragments on immune complexes keeps them from precipitating and promotes their adherence to red blood cells (RBCs) for a hand-off to monocytes and dendritic cells in the liver and spleen.

Through these interactions, complement also instructs the adaptive immune response. Antigens decorated by complement proteins are more efficiently taken up by, or held in place for presentation to, monocytes, follicular-dendritic cells, B lymphocytes, and other antigen-presenting cells, thereby resulting in an adaptive immune response (Chapter 35). For example, complement activation is required for an optimal antibody response to most foreign antigens. In this way, the complement system is often called "nature's adjuvant." Individuals lacking a functional complement system are predisposed to bacterial infections, predominantly by encapsulated organisms, including streptococcus, staphylococcus, *Haemophilus* spp, and *Neisseria* spp. Surprisingly, a complete deficiency of C1q, which is an early component of the classical complement

ABSTRACT

"Complement" is an ancient innate immune system. Initially, it was likely designed to handle cellular debris and invasion by pathogens, even in single-cell organisms. In host defense, its two major functions are mediated by opsonization and membrane perturbation (including the lysis of gram-negative bacteria and enveloped viruses). In parallel, small protein fragments (anaphylatoxins) are liberated that engage receptors to promote the inflammatory response. Through these activities, the complement system also serves as nature's adjuvant to trigger the adaptive immune system. The three pathways evolved to work in seconds to protect the circulation from infections. In evolution, lectins and then antibodies became more rapid and specific triggers of their respective pathways. Complete deficiency of a complement system activating component predisposes to recurrent bacterial infections (particularly pneumococcal for early and meningococcal for late pathways) and autoimmunity, namely systemic lupus erythematosus. If a regulator is deficient secondary to a rare genetic mutation, excessive activation in response to a given degree of injury predisposes to paroxysmal nocturnal hemoglobinuria, atypical hemolytic uremic syndrome, and age-related macular degeneration. Therapeutic agents, particularly monoclonal antibodies to components of each of the three major pathways, are in development. A monoclonal antibody to C5 is Food and Drug Administration–approved to treat paroxysmal nocturnal hemoglobinuria, atypical hemolytic uremic syndrome, myasthenia gravis, and neuromyelitis optica spectrum disorder. The complement system's role in the pathophysiology of many chronic inflammatory conditions and in autoantibody-mediated diseases remains to be defined.

pathway, strongly predisposes to autoimmune diseases, particularly systemic lupus erythematosus (SLE).[4] This association suggests that complement is required not only for host defense against foreign agents but also to identify and safely clear self-materials (debris removal), particularly RNA and DNA species[5] in conditions such as rhabdomyolysis.[6]

A remarkable feature of the complement system is that it reacts within seconds (Table 37-2). In less than 2 minutes, it can coat an encapsulated gram-positive bacterium with several million C3b opsonic fragments and lyse gram-negative bacteria by insertion of its terminal components (the membrane attack complex). It works faster if driven by immunoglobulin M (IgM) or IgG binding to an antigen on a microbial membrane to activate and focus the cascade. Antibodies and lectins direct the activation process to the pathogen's surface. Overall, the complement cascade is designed to become engaged on the surface of a pathogen, particularly bacteria. Plasma and membrane *regulators of complement activation* inhibit formation on normal "self" cells.

Much of complement-mediated pathology revolves around the alternative pathway's amplification loop. This loop is key in triggering activation early in an immune response; however, it must be rigorously regulated to prevent activation on normal self and excessive activation on injured self.[7] Approximately half of the proteins associated with the complement system are dedicated to the control of its activation and effector functions, especially to maintain homeostasis of the alternative pathway's amplification loop.

In clinical medicine, the complement system participates in three pathologic processes: (1) an inherited decrease in functional activity leading to increased susceptibility to bacterial infections and to autoimmunity, (2) undesirable tissue damage upon activation by autoantibodies and immune complexes, and (3) excessive activation at sites of tissue injury in individuals carrying genetic variants in regulators (Tables 37-3 and 37-4).

Knowledge of how complement is activated and how it can be controlled points to opportunities for the development of therapeutic agents such as anti-C5 monoclonal antibody therapy, which has been approved to treat complement-dependent hemolytic and autoimmune disorders.

ACTIVATION OF COMPLEMENT

CLASSICAL PATHWAY

The binding of IgM or IgG to a target antigen activates this exceptionally powerful and quick-acting pathway to destroy microbes (Figs. 37-2 and 37-3). The classical pathway reaction cascade is designed to opsonize and perturb the surface membrane of microorganisms. Of course, autoantibodies also trigger this highly efficient classical pathway. Complement action mediated by immune complexes may then lead to cellular and tissue damage. Instructive examples of autoantibodies and complement-mediated diseases are immune hemolytic anemias, myasthenia gravis, and bullous pemphigoid. The basic problem or pathologic defect in this type of human disease is the formation of the autoantibody. A misidentification of self has occurred because of a breaking of tolerance. In this pathologic situation, the complement system is working at the behest of the autoantibody.

TABLE 37-1 COMPLEMENT SYSTEM IN HOST DEFENSE AGAINST BACTERIA AND VIRUSES

THE ACTIVITY	THE PLAYERS
Opsonization	(C3b > C4b, C1q, MBL)*
Membrane perturbation including lysis (the membrane attack complex)	(C5b-C9)
Pro-inflammatory via cellular activation (the anaphylatoxins and their receptors)	(C3a, C4a, C5a)

*C3b is the major opsonin of the complement system. C1q and MBL (mannose- or mannan-binding lectin) both participate in classical and lectin pathway activation, respectively, but also bind to their specific receptors upon attachment to a target.

TABLE 37-2 SALIENT FEATURES OF THE COMPLEMENT SYSTEM

- Ancient innate system of immunity predominantly found in blood (the "guardian of the intravascular space")
- Capable of rapidly opsonizing and lysing bacteria and viruses (millions of active fragments can be deposited on a target)
- Works in seconds!
- Most proteins are synthesized by the liver, but local production is also important to outcomes
- Constantly turning over (AP protein C3 "ticks over" at a rate of 1 to 2%/hr)
- The AP also features a feedback or amplification loop, which requires tight control
- Effector arm of the humoral immune system (IgM, IgG, and IgA)
- Critical for clearance of self-debris (garbage removal)
- After immunoglobulins and albumin, complement proteins are among the most abundant in blood
- Nature's adjuvant (almost all foreign antigens are coated with complement fragments); instructs the adaptive immune response
- A deficiency of an activator leads to bacterial infections or autoimmunity (SLE)
- A deficiency of a regulator leads to undesirable cellular and tissue damage at sites of injury or degeneration (excessive activation): atypical hemolytic uremic syndrome, age-related macular degeneration

aHUS = atypical hemolytic uremic syndrome; AMD = age-related macular degeneration; AP = alternative pathway; Ig = immunoglobulin; SLE = systemic lupus erythematosus.

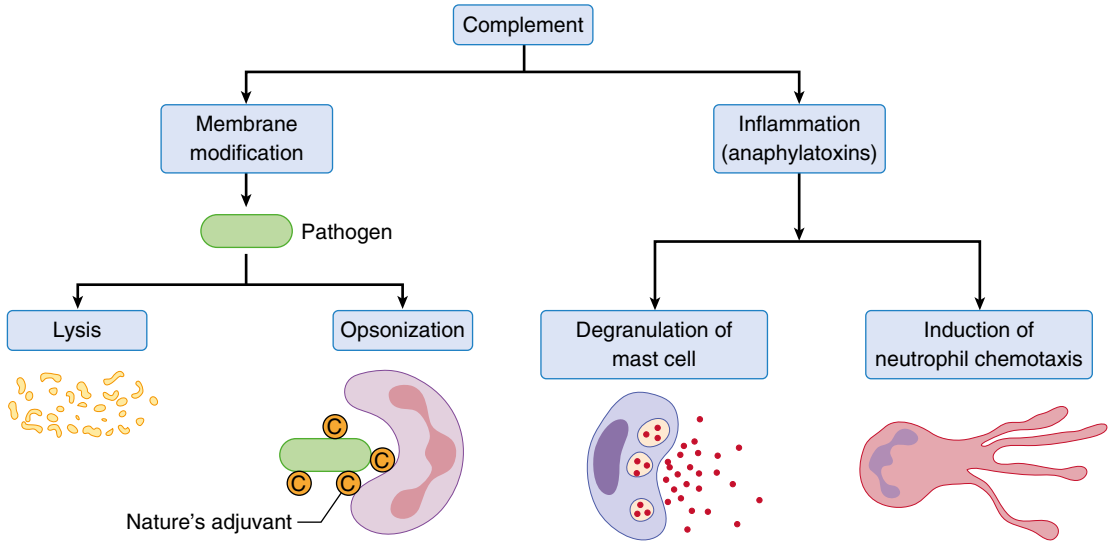

FIGURE 37-1. Function of the complement system. The most important function of the complement system is to alter the membrane of the pathogen by coating its surface with clusters of activation fragments. In one case, they facilitate the key process of opsonization in which C4b and C3b interact with complement receptors. In the other case, as with certain gram-negative bacteria and viruses, the membrane attack complex lyses the organism. The second critical function of complement is to activate cells and thus promote inflammatory and immune responses. The complement fragments C3a and C5a (known as anaphylatoxins) stimulate many cell types such as mast cells to release their contents and stimulate phagocytic cells to migrate to sites of inflammation (chemotaxis) and T cells to modulate metabolism and promote polarization. Through these phenomena of opsonization and cell activation, complement serves as nature's adjuvant to prepare, facilitate, and instruct the host's adaptive immune response. Because extracellular complement activation occurs in a few seconds, this innate immune system initially engages most pathogens, especially those that try to enter the vascular space. As will be illustrated, these basic functions are also required to handle immune complexes and prevent autoimmunity. (Modified from Arthritis Foundation. *Primer on the Rheumatic Diseases*, 12th ed. Atlanta, GA: Arthritis Foundation; 2001.)

The classical pathway is also activated by means other than the formation of IgM- and IgG-bearing immune complexes. β-Amyloid in the neuritic plaques of patients with Alzheimer disease directly engages the classical pathway via an interaction with C1q (Table 37-5). Likewise, C-reactive protein (CRP) and serum amyloid protein bind to chromatin and other ribonucleoprotein complexes released from apoptotic cells, and these types of complexes activate the classical pathway. The classical pathway also plays a key role in the opsonization and removal of nuclear debris. Approximately 80% of patients with hereditary absence of C1q or C4 develop SLE. Deposits of CRP and activated C1 have been demonstrated in ischemic tissue such as infarcted human myocardium. These observations indicate that classical pathway activation via these antibody-independent means is critical in protecting against autoimmune responses by facilitating debris clearance.

Regulation of classical pathway activation occurs at two levels. First, the *ser*ine *p*rotease *in*hibitor (serpin) known as the C1-inhibitor (C1-INH) blocks the activity of many proteases, including factor XIIa, kallikrein, and factor XIa of the clotting system as well as C1r, C1s, and MASP2 of the complement system. The importance of C1-INH is exemplified by its role in hereditary angioedema (Table 37-6). In this dominantly inherited disease, a deficiency of C1-INH allows uncontrolled proteolysis of C4 and C2 and generation of bradykinin, leading to recurrent swelling episodes. This serpin prevents chronic activation of the classical pathway cascade and, after a few minutes, helps to shut down the system. Classical pathway activation is also regulated by multiple inhibitors at the key step of C3 activation. These plasma and membrane proteins inhibit C3 convertase formation on healthy self. Membrane regulators are highly expressed on most cell types, where they prevent activation on normal self and overexuberant activation on altered self.

TABLE 37-3 PARTICIPATION OF THE COMPLEMENT SYSTEM IN HUMAN DISEASE

Activation by autoantibody (formation of immune complexes)
Engagement with modified self (clearance of debris or garbage) • Degenerative processes (diseases of aging such as age-related macular degeneration) • Cell and tissue damage (ischemia-reperfusion injury; atypical hemolytic uremic syndrome)

TABLE 37-4 PATHOLOGIC CONDITIONS ASSOCIATED WITH COMPLEMENT ACTIVATION

Examples of diseases in which complement activation contributes to the immunopathology:
Atypical hemolytic uremic syndrome*†
Paroxysmal nocturnal hemoglobinuria†
Age-related macular degeneration*†
Membranoproliferative glomerulonephritis (types 1, 2, and 3)†‡
Myasthenia gravis‡
Neuromyelitis optica spectrum disorder
Bullous pemphigoid‡
Systemic lupus erythematosus/antiphospholipid syndrome‡
Rheumatoid arthritis‡
Immune hemolytic anemias‡
Immune vasculitis (ANCA-positive syndromes)‡
Ischemia reperfusion injury*†
Allotransplantation‡
Amyotrophic lateral sclerosis†
Transplantation rejection‡
Serum sickness‡
Exposures to foreign materials (e.g., membranes, nanoparticles, gene therapy viruses)*

*Injury, ischemia, trauma, degeneration, or foreign body is the trigger (innate immune activation).
†Lack of adequate regulation contributes to disease pathogenesis.
‡Antibody-dependent activation of the complement system (adaptive humoral immune activation).
ANCA = antineutrophil cytoplasmic antibody.

LECTIN PATHWAY

The protein mannose-binding lectin (MBL) is a member of the collectin family that also includes pulmonary surfactants A and D. MBL has a structure similar to C1q in that it consists of several subunits; namely, a globular recognition head domain for carbohydrates and a collagen-like tail that interacts with serine proteases. In the case of MBL, the globular domain is a lectin (protein) that binds to repeating mannose and *N*-acetylglucosamine residues on the surface of pathogens (see Figs. 37-2 and 37-3). Many microorganisms are recognized by MBL, including gram-positive and gram-negative bacteria, mycobacteria, fungi, parasites, and viruses (including human immunodeficiency virus 1 [HIV-1]). In general, as would be expected, mammalian glycoproteins and glycolipids are not readily recognized by MBL and the related lectins (ficolins and collectins) that activate the lectin pathway.

Three serine proteases, MASP-1, MASP-2, and MASP-3, associate with MBL (and the ficolins and collectins) through their collagen-like domain. This is analogous to the association of C1r and C1s with C1q. Activation of MASP-2, with some help from MASP-1, results in cleavage of C2 and C4, leading to formation of the classical/lectin pathway C3 convertase (C4b2a).

Genetic variations in the structural and regulatory portions of the MBL gene lead to wide differences in serum levels. A low level of MBL is associated with recurrent infections in children and adults and is a risk factor for the development of SLE. More striking is the association of low levels of MBL with infections in the setting of the treatment of SLE. For example, heterozygous MBL deficiency has been associated with a four-fold increase in the risk of bacterial pneumonia and homozygous deficiency with a more than 100-fold increase.[8]

ALTERNATIVE PATHWAY

The alternative pathway takes advantage of the fact that C3 undergoes spontaneous, chronic, low-grade activation (Fig. 37-4; see also Figs. 37-2 and 37-3). This C3b may covalently attach to any cell; however, on normal self, amplification of the cascade is blocked by inhibitors. In contrast, deposition on polysaccharides of bacterial membranes and to other targets, such as endotoxin and virally infected cells, leads to a rapid engagement of this pathway. These sites, similar to immune complexes and almost any type of biomaterial (cardiopulmonary bypass and hemodialysis membranes, nanoparticles, and so on), lack regulators, so rapid, massive activation may occur. IgA also has the capacity to promote activation of the alternative pathway.

During spontaneous activation, called *tickover*, small amounts of activated C3 are continuously generated (C3 turns over in blood at 1 to 2%/hour). It can initiate a feedback loop and cleave more C3 to C3b. Also, the initial C3b may be derived from either the classical or lectin pathway. Thus, activation of complement by any one of the three pathways has the potential to be rapidly magnified. The alternative pathway C3 convertase is negatively controlled (to maintain homeostasis), both in the fluid phase and on host cells, by two abundant plasma proteins and two widely expressed membrane proteins.[9]

The central role of the alternative pathway as an amplifier of complement activation is borne out by its association with a number of clinicopathologic states in the setting of deficient regulation (Tables 37-6 and 37-7). For example, multiple forms of membranoproliferative glomerulonephritis (Chapter 107)

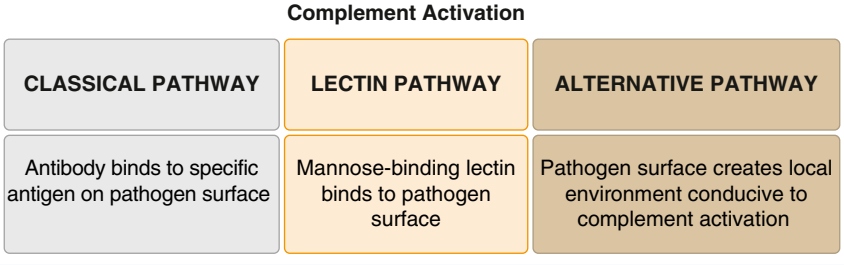

FIGURE 37-2. The three pathways of complement activation. The system is designed to be most efficient on a membrane surface. However, complement activation in the fluid phase, as, for example, in serum sickness, also occurs. In addition, the alternative pathway is continuously at a low level turning over (tickover) in the fluid phase (see Fig. 37-3).

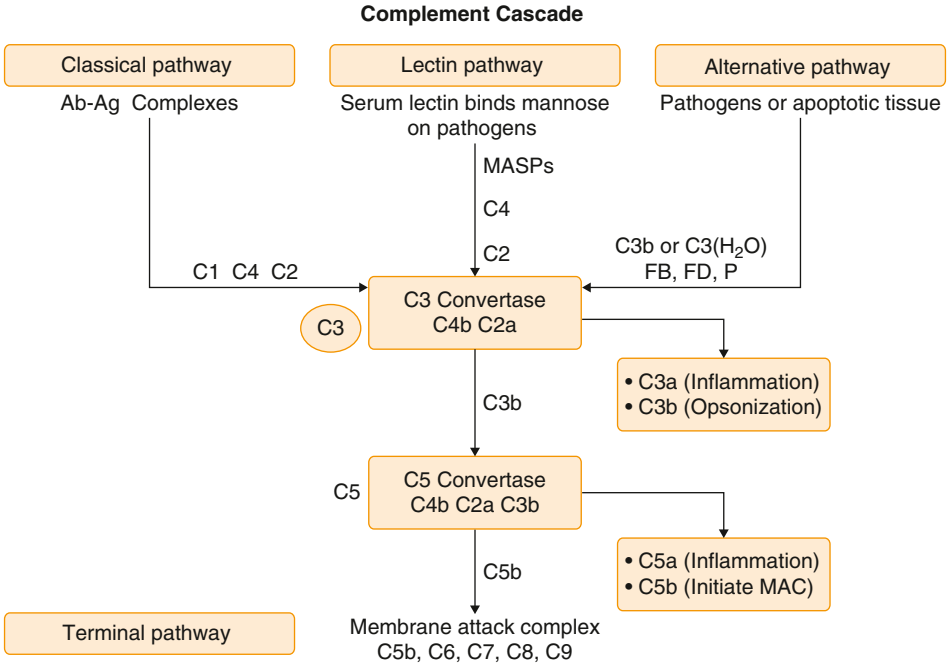

FIGURE 37-3. Classical and lectin pathway activation. Ab = antibody; Ag = antigen; FB = pro-enzyme factor B; FD = protease factor D; MAC = membrane attack complex; MASP = mannan-associated serine protease; P = complement factor P.

TABLE 37-5 TISSUE INJURY OR DEGENERATION AND COMPLEMENT ACTIVATION*

Age-related macular degeneration
Osteoarthritis (degenerative joint disease)
Ischemic stroke
Myocardial infarction
Traumatic injury (e.g., brain, liver, kidney, gut)
Ischemia-reperfusion injury
Burns
Acute respiratory distress syndrome
Septic shock
Multiorgan failure syndromes
Alzheimer disease

*In these conditions, complement activation leads to deposition of fragments at the site of injury; however, how much of the tissue injury is attributable to complement system is unknown. In many cases, animal models support a pathologic role for the complement system. Only in age-related macular degeneration is there also powerful genetic evidence in humans to indicate a key role for the complement system.

are associated with excessive deposition of C3 fragments in the kidney because of either the presence of autoantibodies (C3 or C4 nephritic factors) that stabilize C3 convertases or a genetic deficiency in complement regulatory protein (factor H or factor I). Likewise, atypical hemolytic uremic syndrome[10] (i.e., not associated with a preceding enteropathic infection featuring a Shiga-like toxin) occurs (Chapter 158) in individuals who harbor heterozygous missense mutations in factor H, membrane cofactor protein (MCP), or factor I or have gain-in-function mutations in factor B or C3. Genome-wide association and targeted deep sequencing studies have also linked age-related macular degeneration and diabetic retinopathy[11] (Chapter 391) to functional coding mutations in factor H and factor I and, more uncommonly, in factor B and C3. Finally, rodent models of rheumatoid arthritis, SLE, and antineutrophil cytoplasmic antibody (ANCA)–positive vasculitic syndromes[12] are ameliorated if the alternative pathway is disrupted.

C3 AND C5 CONVERTASES

The three activation pathways converge at C3. A remarkable feature of C3 is the presence of a thioester bond. Buried within the three-dimensional structure of the C3 protein lies a γ-carboxy group of a reactive glutamic acid residue linked to a cysteine in an "internal thioester." Upon its cleavage, for a few microseconds, a covalent attachment can occur via an ester or amide linkage to any nearby hydroxyl or amino group. Most of the cleaved thioester bonds are hydrolyzed by water to produce a form of C3 (known as C3 [H_2O]); however, a substantial percentage forms an amide or ester bond to amino groups or carbohydrates, thereby covalently attaching C3b to a target's surface. Also, the addition of a C3b to C4b2a (classical/lectin pathway C3 convertase) or to C3bBb (alternative pathway C3 convertase) then forms a convertase for C5 (C3bBbC3b for the alternative pathway and C4bC2aC3b for the classical/lectin pathway).

REGULATORS OF COMPLEMENT ACTIVATION AT THE C3 AND C5 STEPS

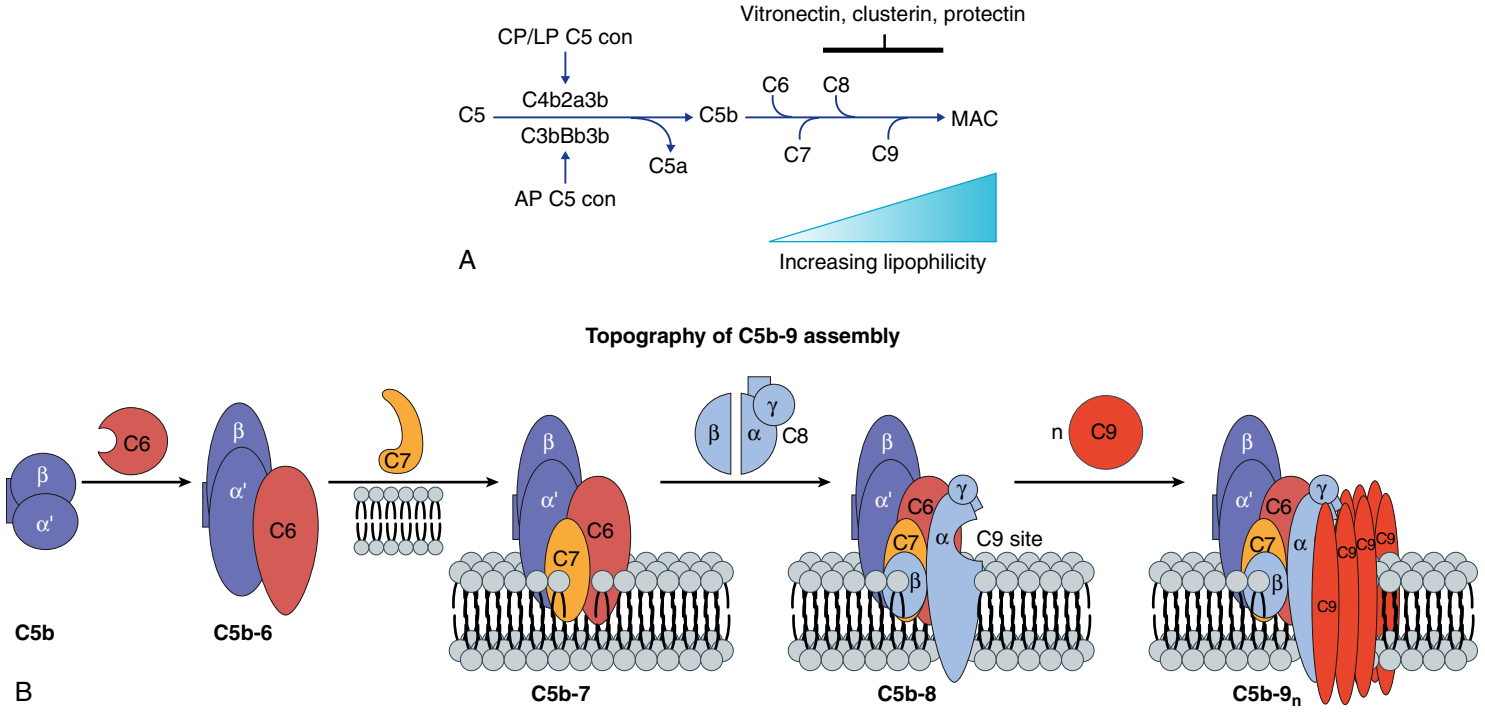
The regulators of complement activation (see Table 37-6) limit the production of C3b, primarily by the alternative pathway C3 convertases. Because the addition of C3b to a C3 convertase makes it a C5 convertase, regulation of the two enzyme complexes is linked. Modulation of their activity on host cells limits tissue destruction and the production of inflammatory mediators.

The complement activation regulatory proteins control complement activation by two processes. *Decay-accelerating activity* refers to when the inhibitor transiently binds to C3b or C4b in the convertase and thereby dissociates the other members of the complex, rendering it enzymatically inactive (as the component released is the catalytic domain of the protease). The second is cofactor activity, which requires recognition of C3b or C4b by a plasma cofactor protein. Upon this interaction, the protease, factor I, cleaves C3b or C4b. Cleavage of C3b by factor I renders the convertase irreversibly inactive (generates iC3b, which cannot participate in convertase formation).

MEMBRANE ATTACK COMPLEX

The cleavage of C5 generates C5a, the most potent of the complement anaphylatoxins, and C5b. C5b associates with C6 and C7 to create a lipophilic trimer as the initial part of the membrane attack complex (see E-Fig. 37-1). The C5b67 trimer inserts into the lipid bilayer and serves as a binding site for C8 and C9. C9 self-polymerizes, leading to 12 to 18 C9 molecules that form a ring structure, completing the membrane attack complex. The membrane attack complex resembles a doughnut with a 10-nm pore running through the center. This pore allows water and ions to enter the cells, ultimately leading to osmotic lysis. Many pathogens such as gram-positive bacteria possess a capsule that makes them resistant to lysis. Opsonization leading to phagocytosis is thus the major means of eliminating such organisms.

The membrane attack complex appears to be essential only for elimination of *Neisseria* spp. Individuals completely deficient in C5, C6, C7, C8, or C9 are at an increased risk only for meningococcal and gonococcal infections (Chapters 274 and 275). C9 deficiency is a common immunodeficiency in Japan, with a heterozygote frequency of 3 to 5%. Thus, heterozygous deficiency seems to not be deleterious to the population in general but may have a selective advantage.



E-FIGURE 37-1. **Activation of C5 and the membrane attack complex (MAC). A,** The C5 convertases (con) are the same as C3 convertases except a C3b has been attached to C4bC2a or a second C3b in the case of alternative pathway (AP) C5 convertase. **B,** Schematic representation of the assembly of the MAC on a cell membrane. C5b (composed of two chains) binds C6 and then C7. The C5b-7 complex can insert into a membrane and then bind C8 (composed of three chains) and multiple C9s to form a pore or channel in the membrane. A complete lack of C5, C6, C7, C8, or C9 predisposes the individual to *Neisseria* infections, especially with the meningococcus (Chapter 274), but no other infectious or immune disorders. Not shown (but see Fig. 37-4) is that properdin stabilizes both C5 convertases and is usually required for efficient C3 and C5 convertase activity. CP = classical pathway; LP = lectin pathway. TABLE 37-6 SOLUBLE AND MEMBRANE FACTORS REGULATING COMPLEMENT

SOLUBLE FACTORS REGULATING COMPLEMENT			
NAME	**LIGAND OR BINDING FACTOR**	**FUNCTIONAL ACTIVITY**	**PATHOLOGY, IF DEFICIENT**
C1-INH	C1r, C1s, mannan-binding lectin-associated serine protease (MASP-2)	Binds to and displaces C1r and C1s from C1q and mannan-binding lectin-associated serine protease (MASP-2) from mannan or mannose binding lectin (MBL)	Hereditary angioedema
C4bp* (C4 binding protein)	C4b, glycosaminoglycans	Displaces C2a (decay-accelerating activity); cofactor for C4b cleavage by factor I (cofactor activity)	No clinical syndrome clearly defined
CPN-1 (carboxypeptidase-N)	C3a, C5a	Inactivates C3a and C5a	Urticaria and angioedema
Factor H*†	C3b, C3d, glycosaminoglycans	Displaces Bb from alternative pathway C3 and C5 convertases (decay-accelerating activity) and is a cofactor for factor I to cleave C3b (cofactor activity)	Age-related macular degeneration, atypical hemolytic uremic syndrome, C3 glomerulopathies, bacterial infections secondary to low C3
Factor I†	C3b, C4b	Serine protease; cleaves C3b and C4b, requires a cofactor protein (cofactor activity)	Age-related macular degeneration, atypical hemolytic uremic syndrome, bacterial infections secondary to low C3
Protein S (vitronectin)	C5b67	Inhibits membrane attachment by C5b67	None defined
MEMBRANE-BOUND FACTORS REGULATING COMPLEMENT			
NAME	**LIGAND OR BINDING FACTOR**	**FUNCTIONAL ACTIVITY**	**DISEASE, IF DEFICIENT**
Decay-accelerating factor (CD55)	C3 and C5 convertases	Prevents binding and displaces Bb from alternative pathway convertase and C2a from CP or LP convertases, respectively	Paroxysmal nocturnal hemoglobinuria Polyneuropathy syndromes CD55 deficiency with hyperactivation of complement, angiopathic thrombosis, and protein-losing enteropathy (CHAPLE syndrome)
Membrane cofactor protein (MCP, CD46)	C3b, C4b	Cofactor for factor I (cofactor activity)	Atypical hemolytic uremic syndrome, immune deficiency
Protectin (CD59)	C8, C9	Inhibits MAC formation and insertion	Paroxysmal nocturnal hemoglobinuria
Complement receptor type 1 (CD35) (immune adherence or C4b/C3b receptor)	C3b, C4b, C3, and C5 convertases	Cofactor for factor I to cleave C4b and C3b (cofactor activity); displaces Bb from C3b and C2a from C4b to inhibit convertases (decay-accelerating activity)	No complete deficiency described; decreased levels in immune complex–mediated diseases such as lupus
Complement receptor of the immunoglobulin superfamily (CRIg)	C3b, iC3b, C3c	Inhibits activation of alternative pathway	None defined

*Factors H and C4bp also bind to surfaces, particularly at sites of tissue and cellular injury, where they carry out regulatory activity.
†If heterozygous deficient, the individual is predisposed to age-related macular degeneration and atypical hemolytic uremic syndrome. If homozygous deficient, the AP turns over excessively, resulting in kidney disease (C3 glomerulopathies) and bacterial infections (secondary to the very low C3).
$(C3b)_2$ Bb = alternative pathway C5 convertase; C3bC4bC2a = classical and lectin pathway C5 convertase; C4bC2a = classical and lectin pathway C3 convertase; MAC = membrane attack complex.

Extensive complement activation during an inflammatory response can result in sufficient membrane attack complex deposition to produce host cell lysis. Host cells, however, have mechanisms in place to resist the osmotic changes caused by the membrane attack complex and to block assembly of the membrane attack complex as it is formed (the protein is known as protectin or CD59). Rather, the nonlethal effects of sublytic membrane attack complex deposition are more likely to contribute to pathology. In most cells, this occurs through a general activation of multiple cell signaling pathways.

The response to membrane attack complex deposition at sites of complement activation depends on the cell type (Table 37-8). In phagocytic cells, such as neutrophils or macrophages, sublytic membrane attack complex insertion leads to the production of reactive oxygen species (e.g., superoxide, hydrogen peroxide) as well as release of prostaglandins and leukotrienes. Platelets undergoing a "membrane attack complex insertion" expose phosphatidylserine on their outer membrane, facilitating assembly of blood coagulation enzyme complexes on their surfaces with a potentially procoagulant effect. On endothelial cells, membrane attack complex deposition induces the synthesis of interleukin-1α (IL-1α), which leads to further autocrine and paracrine endothelial cell activation. It stimulates a procoagulant state by (1) altering the phospholipid composition of the endothelial membrane; (2) inducing the synthesis of tissue factor and upregulating the synthesis of plasminogen activator inhibitor; (3) upregulating the expression of adhesion molecules, including intercellular adhesion molecule 1 (ICAM-1) and E-selectin; and (4) stimulating endothelial cells to proliferate through growth factor production. In summary, although cell death does not usually occur, deposition of the sublytic levels of membrane attack complex leads to a potentially dangerous situation, with increased inflammation, a procoagulant state, and cellular proliferation. Of course, part of this response is necessary at sites of injury to eliminate pathogens and debris and to facilitate wound repair. The short duration of complement activation and the presence of inhibitors help to maintain homeostasis.

Regulation of membrane attack complex formation is important clinically (Fig. 37-5). Two plasma proteins, S-protein (vitronectin) and possibly clusterin, bind the C5b-7 complex and prevent its association with the lipid membrane. C8 and multiple C9 molecules adhere to this soluble complex, termed *soluble C5b-9*, which is lytically inactive. CD59 (protectin) is a membrane-bound inhibitor of membrane attack complex formation. This small glycoprotein is attached to the cell membrane through a glycosyl phosphatidylinositol tail (GPI anchor). It binds to C5b-8, inserted in the cell membrane, to prevent binding to and polymerization of C9. The expression of CD59 is defective in patients with paroxysmal nocturnal hemoglobinuria (Chapter 146), owing to the failure to synthesize the GPI anchor used by this and many other membrane proteins (including decay-accelerating factor [DAF]) to insert on the cell. The clinical features of paroxysmal nocturnal hemoglobinuria are primarily chronic hemolysis and intermittent thrombosis. Hemolysis is caused by complement activation on red cells because of a lack of DAF and particularly CD59. Thrombosis (Chapter 67) is likely secondary to intravascular complement activation, leading to endothelial cell activation. The primary defect is an acquired somatic hematopoietic stem cell mutation of a gene on the X chromosome responsible for encoding the first enzyme in the pathway to synthesize a GPI anchor.

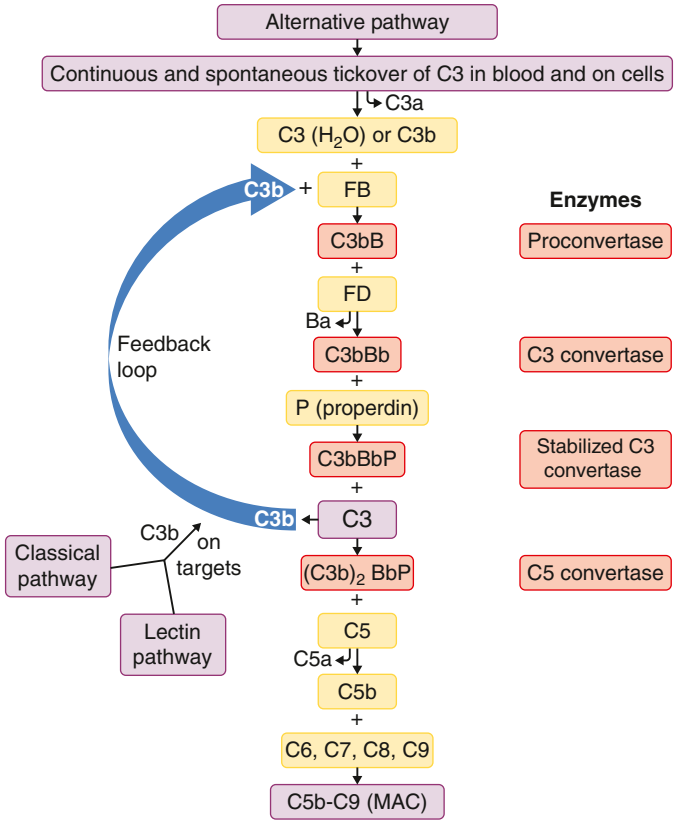

FIGURE 37-4. Complement activation pathways. In the reaction cascade shown, C3b or C3 (H_2O) binds the pro-enzyme factor B (FB), and the C3bB or C3 (H_2O)B complex then is cleaved by the protease factor D (FD). FD is generated by the cleavage of inactive pro-FD to active FD by the protease MASP-3. The addition of properdin (P) to the enzyme complex increases the half-life of the enzyme complex approximately 10-fold. Although the source of the C3b can be from spontaneous turnover or via lectin pathway (LP) and classical pathway (CP) activation, the alternative pathway (AP) feedback loop commonly takes over to generate much of C3b that binds to a target. The alternative pathway is continuously turning over. If activated C3b or C3 (H_2O) remains in the fluid phase, it is rapidly inhibited by the plasma regulators factor H and factor I. If activated C3b binds to normal or healthy self, it is prevented from forming a convertase by the ubiquitously expressed membrane cofactor protein (MCP [CD46]) and decay-accelerating factor (DAF [CD55]) (not shown). DAF both prevents B from binding to C3b and "kicks out" the catalytic Bb domain (a temporary stop), but MCP is a permanent stop because, upon its binding, the C3b is proteolytically cleaved to inactive C3b (iC3b) by the serine protease factor I. The feedback loop is a powerful amplification system. A single *Escherichia coli* organism in blood can be coated with several million C3bs in a couple of minutes!

ANAPHYLATOXINS

The anaphylatoxins serve a key early role in initiating a local inflammatory response as they trigger pathways to prepare a cell to face a pathogen or injury (Table 37-9). Similar to the membrane attack complex, anaphylatoxins are another major source of potential pathologic damage to self that results from complement activation. These peptides, C3a and C5a, are cleaved from their respective proteins during complement activation. They are 77 (C3a) or 74 (C5a) amino acids long and contain a key carboxy (C)-terminal arginine. They interact with the anaphylatoxin receptors. In plasma, the C-terminal arginine is removed by carboxypeptidase-N from anaphylatoxins not bound to their receptors. Depending on the response studied, this removal totally inactivates the anaphylatoxin or reduces its potency by about 1000-fold.

TABLE 37-8 RESPONSES TO SUBLYTIC MEMBRANE ATTACK COMPLEX ACTIVATION

CELL TYPE	EFFECTS
Most cells	Increased intracellular calcium flux Activation of G proteins Activation of protein kinases Activation of transcription factors Proliferation
Neutrophils and macrophages	Release of reactive oxygen species Activation of phospholipase A_2 Release of prostaglandins, thromboxane, and leukotrienes
Platelets	Release of adenosine triphosphate Increased P-selectin expression Procoagulant membrane changes
Endothelial cells	Increased synthesis of IL-1α Increased release of tissue factor Increased release of von Willebrand factor Increased synthesis of basic fibroblast and platelet-derived growth factors
Synoviocytes	Increased synthesis of prostaglandins Increased synthesis of interleukin-6 Increased production of matrix metalloproteinase
Glomerular epithelium	Activation of phospholipase A_2 Synthesis of prostaglandin Increased synthesis of collagen and fibronectin
Oligodendrocytes	Increased synthesis of myelin basic protein and proteolipids Increased proliferation

TABLE 37-7 COMPLEMENT SYSTEM MEDIATES THE DISEASE PROCESS AND ITS INHIBITION TREATS THE CONDITION

DISEASE	PATHOPHYSIOLOGY	ETIOLOGY	TREATMENT	FDA APPROVED
Paroxysmal nocturnal hemoglobinuria (Chapter 146)	Lyse red blood cells	Acquired hematopoietic somatic stem cell mutation in gene required for synthesis of glycosylphosphatidylinositol (GPI) anchor	Monoclonal antibody to C5 Peptide C3 convertase inhibitor	Yes Yes
Atypical hemolytic uremic syndrome (Chapter 158)	Damage to endothelial cells	Inherited loss-of-function variants in alternative pathway regulators or gain of function variants in alternative pathway activators	Monoclonal antibody to C5	Yes
Hereditary angioedema (Chapter 232)	Bradykinin generation	Autosomal dominant variants in the C1-inhibitor gene	C1 inhibitor replacement Bradykinin receptor blockage Kallikrein inhibitors	Yes Yes Yes
Age-related macular degeneration (Chapter 391)	Degeneration of the retina	Inherited variants in a regulator (factor H or factor I) or gain-in-function in an alternative pathway component (C3 or factor B)	Clinical trials in progress	No
Neuromyelitis optica spectrum disorder (Chapter 392)	Damage to spinal cord and optic nerve	Complement-fixing autoantibodies to aquaporin-4 typically found	Monoclonal antibody to C5	Yes
Myasthenia gravis (Chapter 390)	Degeneration of neuromuscular junction	Complement-fixing autoantibodies to acetylcholine receptor	Monoclonal antibody to C5	Yes

FDA = Food and Drug Administration.

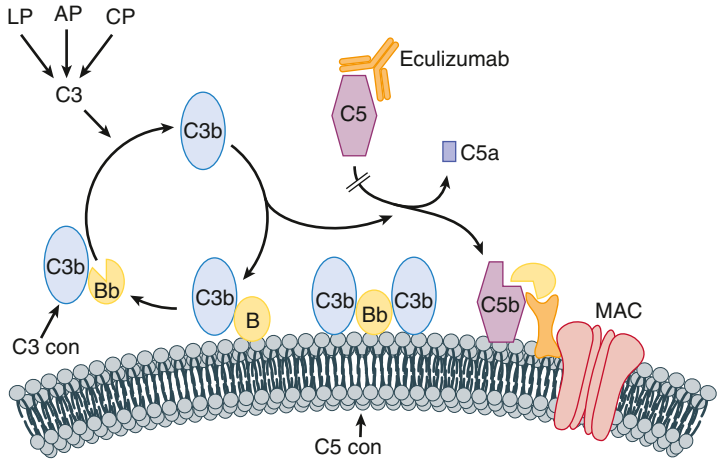

FIGURE 37-5. Complement activation and the mechanism of action of eculizumab (monoclonal antibody [mAb] to C5). The alternative pathway (AP) constantly undergoes "tickover" but can also be primed by the classical pathway (CP) and lectin pathway (LP). The C3b that is formed interacts with factor B (B), which is then cleaved by factor D to form a C3 convertase (C3Bb). As more C3b is generated, a fraction binds to the C3 convertase to form a C5 convertase. Monoclonal antibody to C5 (eculizumab) prevents the cleavage of C5 by the C5 convertase. Not shown is that properdin binds to both the C3 and C5 convertases to increase their half-lives approximately five- to 10-fold (from ≈30 seconds to several minutes). (Modified from Wong EK, Goodship TH, Kavanagh D. Complement therapy in atypical haemolytic uraemic syndrome [aHUS]. *Mol Immunol*. 2013;56:199-212.)

TABLE 37-9 DISTRIBUTION OF ANAPHYLATOXIN RECEPTORS AND THEIR CELLULAR RESPONSES

CELL TYPE	RESPONSES
C5aR (CD88)	
Neutrophils	Chemotaxis
Eosinophils	Enzyme release
Basophils	Generation of reactive oxygen species
Mast cells	Upregulation of adhesion molecules
Monocytes	Increased synthesis of interleukin-1, interleukin-6, and interleukin-8
	Prostaglandin and leukotriene synthesis
Hepatocytes	Increased synthesis of acute phase reactants
Pulmonary epithelium	Increased interleukin-8
Neuronal cells	Cellular activation
Endothelial cells	Increased expression of P-selectin
Renal epithelial/mesangial cells	Proliferation and synthesis of growth factors
C3aR	
Eosinophils	Chemotaxis
Mast cells	Enzyme release
Platelets	Generation of reactive oxygen species
	Upregulation of adhesion molecules
Epithelial, endothelial, etc.	Cellular activation

IL = interleukin.

The C5a receptor (C5aR [CD88]) is a seven-transmembrane-spanning protein that couples ligand binding to G-protein signaling. Expressed on myeloid cells, particularly neutrophils and eosinophils, it mediates the potent chemoattractant property of C5a for both of these cell types. Signaling through CD88 leads to rapid secretion of all granule contents. These contents include lipases and proteases as well as lactoferrin from neutrophils and peroxidase, major basic protein, and cationic protein from eosinophils. C5a also induces the release of cytokines, such as tumor necrosis factor (TNF), IL-1, IL-6, IL-8, and adhesion molecules, promoting the inflammatory response. The C5aR is expressed by numerous other tissues, including hepatocytes, bronchial and alveolar epithelium, vascular endothelium, renal mesangial and tubular epithelial cells, and brain neuronal cells. These cells are activated by receptor engagement, leading to production and release of cytokines, chemokines, and prostaglandins and to cellular proliferation.

The C3a receptor is also a seven-transmembrane-domain protein. It is expressed on almost all myeloid cells, including mast cells, where it mediates the release of allergic mediators. The C3aR also has been detected on many tissues, including in the brain and lung.

The anaphylatoxins have multiple biologic effects. In general, they cause smooth muscle contraction and recruitment of granulocytes, monocytes, and mast cells. In theory, they can contribute to the pathophysiology of any inflammatory condition. In disease models, C3a and C5a have been shown to play a role in diseases such as acute respiratory distress syndrome (ARDS), multisystem organ failure, septic shock, myocardial ischemia-reperfusion injury, ANCA-associated vasculitis, asthma, rheumatoid arthritis, SLE, and inflammatory bowel disease. The anaphylatoxin peptides also are responsible for the "postpump" syndrome seen in patients undergoing cardiopulmonary bypass or hemodialysis. Exposure of blood to dialysis or perfusion membranes leads to complement activation. Within minutes of starting bypass, there is a sharp increase in the levels of C3a and C5a in the extracorporeal circuit being returned to the patient. This increase can be associated with respiratory distress, pulmonary hypertension, and pulmonary edema. It has been shown that the length of time that patients stay on the ventilator after bypass surgery correlates with the level of C3a generated during reperfusion.

C3a and C5a have been implicated in the initiation and prolongation of ARDS (Chapter 90) and multisystem organ failure. After severe trauma, levels of C3a have been measured that suggest activation of the entire circulating C3 pool. This activation leads to bronchoconstriction, increased vascular permeability, hypotension, and vascular plugging with leukocytes. The activation of white blood cells continues the cycle of tissue damage with further complement activation. Continued elevation of C3a in shock or ARDS is a poor prognostic sign. C3a and C5a also appear to play a major role in the pathogenesis of asthma (Chapter 75).

COMPLEMENT RECEPTORS

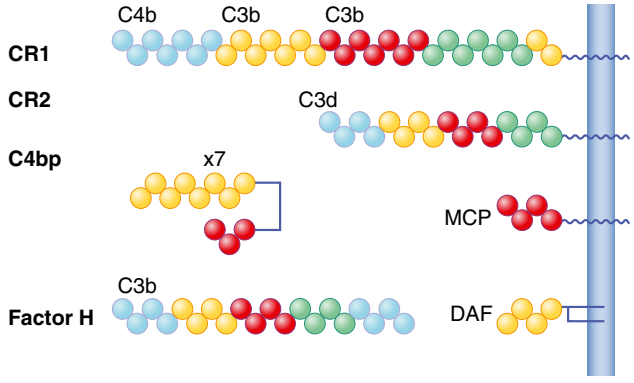
Opsonization of target by C4b and C3b is effective in preventing infections because these two complement fragments (and the further cleavage products in the case of C3b) are ligands for complement receptors (E-Fig. 37-2). After covalent attachment of C4b and C3b, immune adherence occurs between the opsonized microbe and immune cells, predominantly neutrophils, monocytes, and macrophages. Complement opsonins are highly effective mediators of immune adherence. On phagocytic cells, this is the prelude to the ingestion and destruction of the target antigen. On red cells, immune adherence is followed by transfer of the C4b/C3b-coated cargo to monocytes and macrophages in the liver and spleen. CR1 is particularly efficient at immune adherence. Proteolytic modification of C3b leads to iC3b, which is a ligand for the highly phagocytic CR3 and CR4. A further degradation of iC3b to C3d leads to an interaction with CR2 to lower the threshold of B-cell activation. Overall, the process is designed with two goals in mind: (1) destruction by phagocytosis of the microbe and (2) coating of microbial antigens for an adaptive immune response. For example, follicular dendritic cells and B lymphocytes express CR1, CR2, CR3, and CR4 that facilitate complement-coated antigens to be bound, internalized, and presented to other immune cells. CR3 and CR4 facilitate phagocytosis, and CR2 on follicular dendritic cells facilitates immunologic memory generation.

COMPLEMENT INHIBITORS

Given the many disease states in which complement is one of the central mediators of pathology, it is no surprise that complement inhibitors are in preclinical or clinical development for treatment of human diseases (see Table 37-2 and E-Fig. 37-2). These inhibitors take several different forms. Whereas some are variations of physiologic inhibitors, others are the products of molecular biologic searches for novel compounds.[13,14]

It is important to consider where in the complement pathway to design an inhibitor to act. Inhibition of the activation pathways limits the production of biologically active peptides. Inhibiting the activation of C3 not only prevents the generation of the C3a anaphylatoxin but also may leave the patient susceptible to infection by limiting the deposition of C3b on targets as an opsonin. Inhibition of C3b deposition would decrease the patient's ability to clear immune complexes, potentially resulting in renal, pulmonary, and vascular damage. It also might promote the development of antibodies to self-antigens.

Inhibition of the C5 convertases is an attractive goal because it would prevent the generation of the C5a anaphylatoxin and the membrane attack complex (see Fig. 37-5). This strategy would inhibit complement activation without limiting C3b deposition. Inhibitors based on this concept have been successful; the monoclonal antibody to C5 is approved by the U.S. Food and Drug Administration (FDA) to treat paroxysmal nocturnal hemoglobinuria and atypical hemolytic-uremic syndrome (Chapter 158) as well as neuromyelitis optica spectrum disorder (Chapter 392) and myasthenia gravis (Chapter 390).



E-FIGURE 37-2. Model of the complement regulators required to inhibit complement activation on self at the steps of C3 and C5 cleavage. *Circles* represent individual complement control repeats (~60 amino acids each), and *shading* indicates higher organizational units composed of several repeats. The approximate locations for binding of C3b and C4b fragments are indicated. Factor H and C4bp are plasma proteins. C4bp = C4-binding protein; CR = complement receptor; DAF = decay-accelerating factor; MCP = membrane cofactor protein.

Other concerns about complement inhibition include whether it is short or long term and whether it is systemic or local. Long-term inhibition of complement, particularly at one of the early steps, is likely to predispose to infection and possibly autoimmunity. Short-term (hours to days) inhibition at any step is unlikely to cause problems. Given that inflammation is usually a local phenomenon, several mechanisms are being tested to target complement inhibitors to these sites. In this way, higher levels of inhibition can be achieved when needed and with lower doses of inhibitor.

NATURAL COMPLEMENT INHIBITORS

Naturally occurring compounds that control complement activation include products or extracts of plants, fungi, insects, bacteria, viruses, and venoms. The mechanism of complement inhibition by some of these natural products is known and is of clinical and experimental importance. In particular, to protect themselves from the host's complement system, poxviruses, herpesviruses, and flaviviruses produce either mimics of the human regulators that they at one time hijacked from their hosts or proteins that bind the hosts' regulators such as the plasma protein factor H. Bacteria also express a wide variety of inhibitors of the human complement system. *Staphylococcus aureus,* for example, synthesizes up to 10 distinct proteins that inhibit at almost every key step of the complement cascade. Cobra venom factor (CVF) is a modified form of cobra C3b secreted by venom glands in the oral cavity. It is a 144,000-dalton glycoprotein that forms an alternative pathway convertase in association with host factor B. Upon injection, CVF leads to massive activation of the alternative pathway, resulting in shock and pulmonary microvascular injury in experimental animals. It is resistant to the host's inhibitors because the site for that interaction is altered on CVF. Perhaps the most widely used natural inhibitor of complement activation is heparin. It decreases activation of the classical pathway and alternative pathway. In clinical practice, the anticomplementary effect of heparin has been used to prevent complement activation during cardiopulmonary bypass. Measurement of complement activation products such as C3a or soluble C5b-9 after bypass showed decreases of 35 to 70% for adult and pediatric patients when heparin-coated extracorporeal circuits were used. Although numerous studies have looked at the decrease in complement activation by heparin-coated bypass circuits, there have been few attempts to correlate this with clinical outcome.

ANTI-C5
